Optimal Exercise of Executive Stock Options and Implications for Firm Cost

Abstract

This paper conducts a comprehensive study of the optimal exercise policy for an executive stock option and implications for option cost, average life, and alternative valuation concepts. The paper is the first to provide analytical results for an executive with general concave utility. Wealthier or less risk averse executives exercise later and create greater option cost. However, option cost can decline with volatility. We show when there exists a single exercise boundary, yet demonstrate the possibility of a split continuation region. Numerical results show how option cost and average life vary with beta and dividend. Our results yield testable predictions.

Keywords: Executive stock option; Option value; Option life; Exercise policy; Dynamic trading
As options have become a major component of corporate compensation, investors have become increasingly concerned about their cost to firms. The difficulty is that this cost depends on the exercise policies of option holders who face hedging constraints, so standard option theory does not apply. Indeed, evidence indicates that both executives and other employees exercise options well before standard theory would predict.

This paper conducts a comprehensive study of the optimal exercise policy for an executive stock option and its implications for option cost, average life, and alternative valuation concepts. Our paper is the first to provide analytical results on option cost, average life, and the size of the continuation region for an executive with general concave utility. Working in a continuous-time framework, we give conditions under which wealthier or less risk averse executives exercise later and create greater option cost. We prove that the continuation region is smaller the larger the dividend. However, exercise policy is not monotonic in stock return volatility, and option cost to shareholders can decline as volatility rises. We show analytically when the exercise policy is completely characterized by a single stock price boundary; we also demonstrate the possibility of a split continuation region, where the executive exercises only at intermediate stock prices, but not at high or low prices.

When unconstrained trading of outside wealth in the market is possible, our numerical examples with constant relative risk averse utility suggest that the exercise boundary, option cost, and average life increase with the magnitude of the correlation between the stock return and the market return, independent of the sign of the correlation, and approach their levels under the value-maximizing policy. Imposing a bound on the magnitude of the market weight in the outside portfolio reduces boundaries and option values, and when the market risk premium is nonzero, the magnitude of the effect of the portfolio constraint depends on the sign of the correlation. When the market risk premium and stock beta are both nonnegative, increasing the stock beta increases option value.

Recent accounting regulation requiring firms to recognize option expense has intensified the demand for better valuation methods. Until better alternatives emerge, the Financial Accounting Standards Boards (FASB) accepts the use of the Black-Scholes-Merton formula with the option’s contractual term replaced by its average life, and this approximation is used by the vast majority of firms. We compare our model’s option cost with this approximate cost and show how the approximation error varies with the stock beta, volatility, and dividend rate. We find that the error can be large or small, positive or negative. Moreover, in some cases the response of the FASB approximation to a change
in parameters is actually in the wrong direction.

Finally, we examine the option’s subjective value, i.e., its value from the viewpoint of the executive. We provide a general condition under which the subjective value is bounded above by its cost, and prove that subjective option value is decreasing in the dividend payout rate. Our examples show how the subjective discount varies with firm characteristics. The magnitude of the discount suggests that the incentive benefits of option compensation must be large to offset its cost relative to cash compensation.

Overall, our analysis underscores the importance of accurately characterizing the exercise policy for option valuation. As more data on exercises become available, it will be possible to estimate an empirical option exercise and cancellation rate function, and thus deduce option cost empirically. The results of this paper provide guidance about how to specify and interpret models for estimating exercise rates and option cost, and yield testable predictions about option exercise behavior. For example, our results suggest that average option lives should be increasing in non-option wealth and in the dividend rate.

The paper proceeds as follows. Section 1 reviews the related literature. Section 2 presents the general model with optimal trading of outside wealth and analyzes the dividend effect. Section 3 analyzes the effects of risk aversion and wealth and characterizes the shape of the exercise policy for a general utility function in the special case when riskless investment of outside wealth is optimal. Section 4 numerically studies the general case with optimal dynamic trading of outside wealth assuming constant relative risk averse utility and shows how the exercise policy and option cost vary with the correlation between the underlying stock and the market. Section 5 shows how option average life and the FASB approximation error vary with the stock beta, volatility, and dividend payout rate. Section 6 examines the option’s subjective value to the executive and shows how the subjective discount varies with the stock price parameters. Finally, Section 7 concludes.

1 Related literature

The intuition that the need for diversification can lead an executive to sacrifice some option value by exercising early is well understood in the literature, but explicit theory of the optimal exercise of ESOs is still developing. Early papers establish the conceptual foundation for ESO valuation and explain the rationale for value-destroying early exercise. In particular, Huddart (1994) and Marcus and Kulatilaka (1994) present binomial models of the exercise decision and option cost with constant relative risk averse utility and outside
wealth in the riskless asset. Marcus and Kulatilaka (1994) include a positive risk premium on the stock return, so the riskless investment of outside wealth is not optimal and this can create a distortion in the exercise policy. Carpenter (1998) assumes outside wealth is invested in the Merton (1971) portfolio, but this is still not fully optimal in the presence of the option. Detemple and Sundaresan (1999) study the case of simultaneous optimal exercise and portfolio choice decisions and provide a characterization of the solution in terms of certainty equivalents. Some recent papers use specific utility functions to focus on the optimal partial exercise of options. These include Jain and Subramanian (2004), Henderson (2006), Grasselli (2006), and Rogers and Scheinkman (2007). None of these papers contains either general analytical results on option cost and average life or a comprehensive numerical examination of policy and cost with dynamic trading of outside wealth.

Other recent papers have solved versions of the problem we describe here for the case of constant absolute risk averse utility. Kadam, Lakner, and Srinivasan (2003) model the optimal exercise policy for an infinite horizon option, but the model links the manager’s consumption date to the option exercise date, which can distort the exercise decision, even in the absence of trading restrictions. Henderson (2004) also models the optimal exercise policy for an infinite horizon real option and links the manager’s consumption date to the option exercise date, but uses a specialized utility function so that this link does not distort the exercise policy. Leung and Sircar (2007) solve the finite horizon problem, and include the risk of job termination and the possibility of partial option exercise. These papers obtain extensive analytical results under the assumption of constant absolute risk aversion. Our paper allows for a more general utility specification and the study of wealth effects.

A number of papers value options using exogenous specifications of the exercise policy. Jennergren and Näslund (1993), Carr and Linetsky (2000), and Cvitanić, Wiener, and Zapatero (2004) derive analytic formulas for option value assuming exogenously specified exercise boundaries and forfeiture rates. Hull and White (2004) propose a binomial model in which exercise occurs when the stock price reaches an exogenously specified multiple of the stock price and forfeiture occurs at an exogenous rate. Rubinstein (1995) and Cuny and Jorion (1995) also compute option value under exogenous assumptions about the timing of exercise. Given a specific exercise policy, these models are more computationally tractable, but the accuracy of their approximation of option cost is as yet unknown and they provide little insight about how option exercise policy should vary with option holder
and firm characteristics.

Finally, another literature focuses primarily on option subjective value to the executive, and its discount from firm cost. Lambert, Larcker, and Verrecchia (1991) analyzes the case of a European option. Hall and Murphy (2002) allow for early exercise but invest non-option wealth in an exogenously specified portfolio of stock and bonds. Cai and Vijh (2005) fix outside wealth in the optimal constant proportion portfolio. Ingersoll (2006) develops an analytic subjective option valuation methodology assuming a constant relative risk averse executive with a fixed proportion of wealth in restricted stock, a marginal option position and an optimal constant barrier policy. In addition to our contributions to the literature on optimal exercise and option cost, our paper augments this subjective value literature with a comprehensive study of firm parameter effects in a model with optimal dynamic trading.

2 General framework

Options have become a significant part of corporate compensation, now representing over 40% of compensation for top executives at large firms (see Frydman and Saks, 2007). While option compensation is widely believed to create valuable performance benefits, firms, investors, and regulators are also increasingly concerned about its cost, since a better understanding of option cost can help firms decide how to use options most efficiently. Options create performance incentives because option holders cannot sell or fully hedge their options. In particular, options are explicitly nontransferable and Section 16-c of the Securities Exchange Act prohibits corporate insiders from taking short positions in their company’s stock. However, these constraints on hedging mean that the standard American option valuation theory does not apply, because standard theory assumes the option holders can trade freely and thus exercise according to a value-maximizing policy (see, for example, Merton, 1973; Van Moerbeke, 1976; Roll, 1977; Geske, 1979; Whaley, 1981; Kim, 1990). By contrast, constrained option holders exercise options in potentially value-destroying ways in order to diversify away some stock-specific risks.

The use of zero-cost collars and equity swaps by corporate insiders documented by Bettis, Bizjak, and Lemmon (2001) suggests that insiders may have some scope for hedging their incentive compensation. However, evidence that the vast majority of options are exercised well before expiration, even when no dividend is present, suggests that option holders still face significant hedging constraints (see, for example, Bettis, Bizjak, and
Lemmon, 2005).

Although we refer to the option holder as an executive, our formulation of the problem may apply equally well to lower-ranked employees. Non-insiders are not subject to Section 16-c short sales restrictions, but they may still find shorting stock to be quite expensive. Evidence of pervasive early exercise in the full sample of firm employees, documented in Huddart and Lang (1996), suggests that lower-ranked employees also face significant hedging constraints. This section lays out a general model of the executive's optimal exercise problem in the presence of hedging restrictions and defines the resulting option cost to shareholders.

2.1 Executive’s option exercise and portfolio choice problem

The executive has \( n \) finite-lived nontransferable options with strike price \( K \) and expiration date \( T \) and additional wealth \( W \) that can be invested subject to a prohibition on short sales of the stock. The investment set includes riskless bonds with constant riskless rate \( r \), the underlying stock with price \( S_t \), and a market portfolio with price \( M_t \). These prices satisfy

\[
\frac{dS_t}{S_t} = (\lambda - \delta) \, dt + \sigma \, dB_t, \quad (1)
\]

\[
\frac{dM_t}{M_t} = \mu \, dt + \sigma_m \, dZ_t, \quad (2)
\]

where \( B \) and \( Z \) are standard Brownian motions with instantaneous correlation \( \rho \) defined on a complete probability space equipped with the natural filtration. The stock return volatility, \( \sigma \), the stock dividend rate \( \delta \), and the mean and volatility of the market return, \( \mu \) and \( \sigma_m \), are constant. The mean stock return \( \lambda \) is equal to the normal return for the stock given its correlation with the market,

\[
\lambda = r + \beta (\mu - r),
\]

where the \( \beta = \rho \sigma / \sigma_m \). In particular, in the absence of the option, an optimal portfolio would contain no stock position beyond what is implicitly included in the market portfolio.

The executive simultaneously chooses an option exercise time \( \tau \), which is a stopping time of the filtration generated by the Brownian motion, and an outside wealth investment strategy in the market and the stock, \( \pi_t \equiv (\pi_t^m, \pi_t^s) \), satisfying \( \mathbb{E} \int_0^T \| \pi_t \|^2 \, dt < \infty \). His
goal is to maximize the expected utility of time $T$ wealth, or equivalently:

$$\max_{\{t_v \leq \tau \leq T, \pi^m, \pi^s \geq 0\}} \mathbb{E}\{V(W^\pi_{\tau} + n(S_{\tau} - K)^+, \tau)\} \tag{4}$$

where $t_v$ is the option vesting date, $W^\pi$ denotes the outside wealth process under trading strategy $\pi$ given by

$$dW^\pi_t = rW^\pi_t\, dt + \pi^m_t((\mu - r)\, dt + \sigma_m\, dZ_t) + \pi^s_t((\lambda - r)\, dt + \sigma\, dB_t), \tag{5}$$

$V$ is the indirect utility of freely investable wealth,

$$V(W_t, t) \equiv \max_{\pi^m} \mathbb{E}_t\{U(W_T)\} \text{ s.t. } dW_u = rW_u\, du + \pi^m_u((\mu - r)\, du + \sigma_m\, dZ_u), \tag{6}$$

and the utility function $U$ is strictly increasing, strictly concave, and twice continuously differentiable. Intuition suggests that the optimal outside position in the stock in problem (4) is $\pi^s \equiv 0$. However this remains to be proved.

This formulation entails a number of simplifications. The executive’s portfolio does not include a position in restricted shares of stock (see Kahl, Liu, and Longstaff, 2003; Ingersoll, 2006, for models of portfolio choice with restricted stock). It allows only for a single block exercise of the option, although the executive would probably prefer to exercise the options at a stochastic rate over time. The model also considers only a single grant of options when in practice, executives are granted new ten-year options every year and typically build up large inventories of options with different strikes and expiration dates. It would be useful to understand which options are most attractive to exercise first and how the anticipation of future grants of options and other forms of compensation affects current exercise decisions. In addition, the model does not account for any control the executive has over the underlying stock price process through the exertion of effort and through project and leverage choices; these choices may interact with the exercise decision. Finally, the model does not incorporate the possibility of forfeiture or cancellation. This would require assumptions about the utility payoff in those events, to which the results might be sensitive. Despite these simplifications, we believe this formulation captures the essence of the executive stock option problem.
2.2 Option cost to shareholders and executive’s subjective value

The solution to the executive’s optimal exercise problem, that is, the optimal exercise policy $\tau$, defines the option payoff, $(S_\tau - K)^+$ that occurs at time $\tau$. The cost of the option to shareholders who can trade freely is the present value, or replication cost, of that payoff. This can be represented as the risk-neutral expectation of the risklessly discounted option payoff,

$$P = E^*\{e^{-r\tau}(S_\tau - K)^+}\},$$

where $E^*$ means the expectation is taken with respect to the probability measure under which the expected returns on both the market and the stock are equal to the riskless rate.

Standard theory for tradeable options assumes the option holder chooses the exercise policy to maximize the option’s present value, because when the option is tradeable, maximizing present value is consistent with maximizing expected utility. When the option is nontransferable these objectives are different, and the utility-maximizing payoff typically has a lower present value.

In addition, when the option is nontransferable, its present value or cost to shareholders is different from its subjective value to the executive. We define the subjective option value as the amount of freely investable money that would give the executive the same utility as the option, i.e., the value of $x$ such that

$$V(W + x, t) = f(W, S, t),$$

where $V$ is the indirect utility value of freely investable wealth as defined in Equation (6), and $f$ is the value function for the executive’s problem with the options, defined formally below. This definition is consistent with that in Kahl, Liu, and Longstaff (2003) for the subjective value of restricted stock. Section 6 proves that this must be less than the option cost to shareholders and provides some examples. The discount in the executive’s valuation of the option relative to its cost to shareholders is part of the price shareholders pay for improved performance benefits relative to cash compensation.

2.3 Exercise policy and the effect of dividends

The cost of the executive stock option depends on the executive’s exercise policy. In the Markovian setting here, we can describe the exercise policy in terms of the so-called
continuation region of the executive, the set of states in which he continues to hold the option. Formally, the value function for the executive’s problem is

\[ f(W_t, S_t, t) \equiv \sup_{\{\nu,t \leq \tau \leq T, \pi^m, \pi^s \geq 0\}} E_t\{V(W^\pi_\tau + n(S_\tau - K)^+, \tau)\} \]  

and the executive’s continuation region is the set

\[ D \equiv \{(w, s, t) : t < t_v \text{ or } f(w, s, t) > V(w + n(s - K)^+, t)\}. \]

The nature of the present value-maximizing continuation region for an ordinary American option is well known (see, for example, Kim, 1990). There exists a critical stock price boundary above which the option holder exercises and below which he waits. The boundary is increasing in the stock return volatility and time to expiration and decreasing in the dividend rate. For an executive stock option, some of these results may fail to hold. However, the dividend effect is the essentially the same.

**Proposition 1** The executive’s continuation region is larger the smaller the dividend rate on the stock.

**Proof** Suppose a given state \((w, s, t)\) with \(t \geq t_v\) is in the continuation region when the dividend rate is \(\delta_1\) and let \(\delta_2 < \delta_1\). Let \(f(w, s, t; \delta)\) denote the value function and \(S^{(\delta)}_t\) denote the stock price process when the dividend rate is \(\delta\). For every strategy \(\pi\) and \(\tau\),

\[ V(W^\pi_\tau + n(S^{(\delta_2)}_\tau - K)^+, \tau) \geq V(W^\pi_\tau + n(S^{(\delta_1)}_\tau - K)^+, \tau), \]  

where \(W^\pi\) denotes the outside wealth process under trading strategy \(\pi\). This implies

\[ \sup_{\pi, \tau} E_t V(W^\pi_\tau + n(S^{(\delta_2)}_\tau - K)^+, \tau) \geq \sup_{\pi, \tau} E_t V(W^\pi_\tau + n(S^{(\delta_1)}_\tau - K)^+, \tau), \]

so

\[ f(w, s, t; \delta_2) \geq f(w, s, t; \delta_1) > V(w + n(s - K)^+, t). \]

Therefore, \((w, s, t)\) is in the continuation region for \(\delta_2\).

Note that this result holds regardless of the shape of the continuation region or the existence of a critical stock boundary. Numerical examples described later show that, like the value of ordinary options, executive option cost decreases in the dividend rate. The inequality \(f(w, s, t; \delta_2) \geq f(w, s, t; \delta_1)\) above also implies the following:
Proposition 2  The executive’s subjective option value is greater the smaller the dividend rate on the stock.

3  Special case with no portfolio choice

The presence of the outside portfolio choice problem significantly complicates the analysis, and most of our remaining results for this general case are numerical. Before turning to those, we develop additional analytical results for the special case in which the optimal portfolio choice is simply to invest in riskless bonds. To make riskless bonds the optimal investment for outside wealth, it is necessary to eliminate the correlated market asset and also the risk premium on the stock. Otherwise, if the stock has a positive risk premium, the investor will desire a long stock position in some states of the world, and forcing his outside wealth to be in bonds will create a spurious motive for holding the option attributable solely to an artificial constraint on long stock positions. To avoid this distortion, we consider the case in which the stock appreciates at the riskless rate,

\[ \frac{dS_t}{S_t} = (r - \delta) \, dt + \sigma \, dB_t, \]  

(14)

and there is no other risky asset available. In this case, it is clear that after the executive exercises the options, his optimal portfolio contains only riskless bonds, so

\[ V(W_t, t) = U(W_t e^{r(T-t)}). \]  

(15)

Intuition suggests that, even before the option is exercised, the executive’s optimal outside portfolio contains no stock, since he would choose to short stock in the absence of a short sale constraint.

We proceed with the assumption that investing outside wealth in bonds is optimal here. The executive’s problem at each time \( t < T \) then becomes

\[ f(S_t, t) \equiv \max_{\{t \leq \tau \leq T\}} \mathbb{E}_t \{ U(n(S_{\tau} - K)^+e^{r(T-\tau)} + W) \}, \]  

(16)

where the constant \( W \) is outside wealth at time \( T \) and \( f : (0, \infty) \times [0, T] \to \mathcal{R} \) is a continuous function satisfying \( f(S_t, t) \geq U(n(S_t - K)^+ + W) \) and \( f(S_T, T) = U(n(S_T - K)^+ + W) \).
Note that
\[
\mathbb{E}[\sup_{0 \leq t \leq T} U(n(S_t - K)^+ e^{r(T-t)} + W)] = \mathbb{E}[U(\max_{0 \leq t \leq T} (n(S_t - K)^+ e^{r(T-t)} + W))] 
\leq U(\mathbb{E}[\max_{0 \leq t \leq T} (n(S_t - K)^+ e^{r(T-t)} + W)])
\]
\[
\leq \infty,
\]
so Theorem D.12 of Karatzas and Shreve (1998) implies that an optimal exercise time is
\[
\tau^* \equiv \inf \{t \in [t_v, T] : f(S_t, t) = U(n(S_t - K)^+ e^{r(T-t)} + W)\}.
\]
The continuation region for the problem is
\[
D = \{(s, t) \in (0, \infty) \times [0, T] : t < t_v \text{ or } f(s, t) > U(n(s - K)^+ e^{r(T-t)} + W)\}.
\]
In the continuation region, \(f(S, t)\) satisfies \(E(df) = 0\). If \(f\) is \(C^{2,1}\) then, by Ito’s Lemma, it satisfies the p.d.e.
\[
f_t + \frac{1}{2} \sigma^2 S^2 f_{SS} + (r - \delta) S f_S = 0.
\]
To calculate \(f\) numerically, simultaneously determining the optimal exercise policy, we solve Equation (22) backwards using an implicit finite difference method, similar to valuing an ordinary American option. The market value of the option, \(P(S, t)\), solves the usual Black-Scholes equation,
\[
P_t + \frac{1}{2} \sigma^2 S^2 P_{SS} + (r - \delta) SP_S - rP = 0,
\]
subject to the exercise policy determined in solving for \(f\).

### 3.1 Existence of a single stock price boundary

This section explores whether a single stock price boundary \(\bar{s}(t)\) separates the continuation region below from the exercise region above, as is the case for ordinary American calls. This is often assumed to be true in executive stock option models with exogenously specified exercise policies. However, we show that the utility-maximizing policy need not have this structure and provide conditions under which it does.

To formalize intuition about the various effects of waiting to exercise, let \(g(s, t) \equiv \)
$U(n(s - K) + e^{r(T-t)} + W)$ denote the payoff function for the optimal stopping problem and note that on $(K, \infty) \times [0, T]$, $g$ is $C^{2,1}$ and Itô’s lemma implies that $g$ has drift equal to $H(S_t, t)$ where

$$H(s, t) \equiv U'(h(s, t))(rK - \delta s)n e^{r(T-t)} + \frac{1}{2} U''(h(s, t))n^2 e^{2r(T-t)}\sigma^2 s^2$$

(23)

and $h(s, t) \equiv n(s - K)e^{r(T-t)} + W$ is total time $T$ wealth given exercise at time $t$ and stock price $s$. This expression shows that when the option is in the money, the effects of waiting to exercise include the benefits of delaying payment of the strike price, the cost of losing dividends, and the cost of bearing stock price risk.

**Proposition 3** Suppose that $W > nKe^{rT}$ and $H$ is nonincreasing in the stock price $s$. Then for each time $t \in [t_v, T)$, if there is any stock price at which exercise is optimal, then there exists a critical stock price $\bar{s}(t)$ such that it is optimal to exercise the option if and only if $S_t \geq \bar{s}(t)$.

**Proof** Fix $t \in [t_v, T)$. Suppose $(s_1, t)$ is a continuation point. We show that if $s_2 < s_1$ then $(s_2, t)$ is also a continuation point. First note that it must be optimal to continue holding the option if $S_t \leq K$. Stopping then would guarantee a reward of $U(W)$, which is less than the expected utility of continuing, for example, until the first time the stock price rises to $K + c$, for some $c > 0$, or until expiration $T$.

So assume $s_1 > s_2 > K$. For $u \geq t$, let $S_u^{(1)}$ denote the stock price process starting from $s_i$ at time $t$ and note that $S_u^{(1)} > S_u^{(2)}$. Finally, let $\tau$ be the optimal stopping time given $S_t = s_1$. Since $\tau$ is a feasible strategy if $S_t = s_2$,

$$f(s_2, t) - f(s_1, t) \geq E_t \left( U(n(S_t^{(1)}) - K)^+ e^{r(T-\tau)} + W) - U(n(S_t^{(2)} - K)^+ e^{r(T-\tau)} + W) \right)$$

$$\geq E_t \left( U(n(S_t^{(2)} - K)e^{r(T-\tau)} + W) - U(n(S_t^{(2)} - K)e^{r(T-\tau)} + W) \right)$$

$$= g(s_2, t) - g(s_1, t) + E_t \int_t^\tau \left( H(S_u^{(2)}, u) - H(S_u^{(1)}, u) \right) du$$

$$\geq g(s_2, t) - g(s_1, t).$$

(24)

Therefore, $f(s_2, t) - g(s_2, t) \geq f(s_1, t) - g(s_1, t) > 0$.

The hypothesis is satisfied for constant relative risk averse utility functions with relative risk aversion less than or equal to one and sufficiently large wealth. Similarly, in the value maximization problem for an ordinary option, the second order term in $H$ does not appear, the drift is nonincreasing in the stock price, and it follows that it is optimal to
exercise if and only if the stock price has risen above a critical level. For executive stock options however, the risk aversion of the option holder gives rise to the second order term, and the drift need no longer be monotonic in the stock price.

**Example with a split continuation region** Figure 1 shows the optimal exercise policy for utility function

\[ U(W) = \frac{W^{1-A}}{1-A} + cW \]  

with \( A = 10, c = 0.0001, K = 1, t_v = 5, T = 10, r = 0.05, \sigma = 30\%, \) and \( \delta = 0. \) The utility function is strictly increasing and strictly concave. As the figure shows, the executive exercises the option for intermediate stock prices, but does not exercise at either high or low stock prices. The intuition for this is that as the stock price grows large, the executive feels wealthier, the concave part of his utility becomes small relative to the risk neutral part, he starts to act like a value maximizer, and refrains from exercising because the dividend rate is zero. With a positive dividend rate, there would also be another exercise region, above the upper continuation region, extending to infinity. In this example, if we ignore the presence of the upper continuation region, the option cost is 0.408 instead of the correct value of 0.432.

Ahn and Wilmott (2003) find an example with a disconnected continuation region using a specialized HARA utility function and no outside wealth, but it requires that the appreciation rate on the stock exceed the riskless rate. This can distort the exercise policy when the model does not permit the executive to buy stock, because he may choose to continue holding the option as a substitute, even when doing so is value-destroying.

### 3.2 Risk aversion, wealth, and volatility effects

This section describes how exercise policy and option cost change with risk aversion, wealth, and stock return volatility.

#### 3.2.1 Monotonicity with respect to risk aversion and wealth

Intuition suggests that less risk averse managers are likely to exercise later, and consequently the cost of their options is greater. Similarly, one would expect that managers with decreasing absolute risk aversion will exercise later, implying greater option cost, if they have more non-option wealth. The following results verify this intuition and hold regardless of the actual shape of the continuation region:
**Proposition 4** An executive with less absolute risk aversion has a larger continuation region.

**Proof** If $U_1$ and $U_2$ are utility functions and $U_2$ has everywhere less absolute risk aversion than $U_1$, then by Theorem 5 on page 40 of Ingersoll (1987),

$$U_2(W) = G(U_1(W)), \quad (26)$$

where the function $G$ satisfies $G' > 0$ and $G'' > 0$. Now suppose a given state $(s, t)$ with $t \geq t_v$ is in the continuation region for the problem with utility $U_1$, and let $\tau$ be the optimal stopping time for $U_1$. Let $f_i(s, t)$ and $g_i(s, t)$ denote the value and payoff functions for the problem with utility $U_i$, $i = 1, 2$. Since $\tau$ is feasible for the problem with $U_2$,

$$f_2(s, t) - g_2(s, t) \geq E_t\{U_2(n(S_\tau - K)^+e^{r(T-\tau)} + W)\} - U_2(n(S_t - K)^+e^{r(T-t)} + W)$$

$$= E_t\{G(U_1(n(S_\tau - K)^+e^{r(T-\tau)} + W))\} - G(U_1(n(S_t - K)^+e^{r(T-t)} + W))$$

$$\geq G(E_t\{U_1(n(S_\tau - K)^+e^{r(T-\tau)} + W)\}) - G(U_1(n(S_t - K)^+e^{r(T-t)} + W))$$

$$= G(f_1(s, t)) - G(g_1(s, t))$$

$$> 0. \quad (27)$$

Therefore, $(s, t)$ is also in the continuation region for $U_2$.

**Corollary 1** If the executive has decreasing absolute risk aversion, then the continuation region is larger with greater wealth.

**Proof** Let $W_2 > W_1$ and note that $U(w + W_2 - W_1) = G(U(w))$ for some function $G$ satisfying $G' > 0$ and $G'' > 0$.

Note that when the the stock price process is the same, but the continuation region is larger, the realized time to exercise or expiration is greater, and thus the option’s expected life is greater. This leads to the following two corollaries:

**Corollary 2** The expected life of the option is greater if the executive has less absolute risk aversion.

**Corollary 3** If the executive has decreasing absolute risk aversion, then the expected life of the option is greater if the executive is wealthier.
This yields the testable prediction that the options of wealthier executives have longer average lives.

**Proposition 5** If the dividend is zero, option cost is greater if the executive has less absolute risk aversion.

**Proof** Suppose $U_1$ and $U_2$ are utility functions and $U_2$ has everywhere less absolute risk aversion than $U_1$. For $i = 1, 2$, let $\tau_i$ be the optimal stopping time for the executive with utility $U_i$ and let $P_i$ be the resulting option cost. Finally, let

$$p(s, t) \equiv e^{-rt}(s - k).$$

By Proposition 4, $\tau_2 \geq \tau_1$, so

$$P_2 - P_1 = E\{p(S_{\tau_2}, \tau_2)^+ - p(S_{\tau_1}, \tau_1)^+\} = E\{(p(S_{\tau_2}, \tau_2)^+ - p(S_{\tau_1}, \tau_1)^+)_1\{\tau_1 < T\}\} \geq E\{(p(S_{\tau_2}, \tau_2)^+ - p(S_{\tau_1}, \tau_1)^+)_1\{\tau_1 < T\}\} = E\{\int_{\tau_1}^{\tau_2} e^{-rt}(rK dt + \sigma S_t dB_t)_1\{\tau_1 < T\}\} \geq 0.$$

**Corollary 4** If the executive has decreasing absolute risk aversion and the dividend is zero, then option cost is greater with greater wealth.

**Proof** From Corollary 1, the optimal stopping time for an executive with greater wealth is later. The rest follows like the proof of Proposition 5.

In numerical examples with constant relative risk averse utility, option cost decreases in risk aversion and increases in wealth with a positive dividend as well. All of the examples described in this section are generated using an implicit finite difference method to solve the partial differential equations describing the executive value function and option cost. Even in examples in which the coefficient of relative risk aversion, $A$, is greater than one, or wealth is small, the continuation region is characterized by a single stock price boundary.
Figures 2 and 3 illustrate these effects with plots of exercise boundaries and option cost for various levels of risk aversion and wealth. On the left, the exercise boundary for each level of risk aversion is a plot of the critical stock price $\bar{s}(t)$ versus time $t$. On the right, the option values, labeled “ESO value,” determined by the different boundaries are plotted against the level of risk aversion. Shown for comparison, the option value labeled “Max value” is the value of the option under the usual present value-maximizing policy. In all of the figures, the options are at the money and the number of options and initial stock price are normalized to one.

Consistent with Propositions 4 and 5 and Corollaries 1 and 4, the exercise boundaries and option values fall with risk aversion and rise with wealth. The examples also suggest that as risk aversion grows large, or as outside wealth goes to zero, the boundary falls to $S = K$ and option value falls to zero (or the value of a European option that expires on the vesting date). The intuition for this is that as risk aversion grows large, the risk premium required to trade a certain exercise value for a risky continuation value goes to infinity. On the other hand, as risk aversion goes to zero, or as wealth grows large, option value converges to the present-value maximizing value.

3.2.2 Non-monotonicity with respect to the stock return volatility

A basic result in standard option pricing theory is that option value is increasing in volatility. This is also typically the case in executive stock option models with an exogenously specified exercise boundary that does not change with volatility (see, for example, Cvitanić, Wiener, and Zapatero, 2004). However, the utility-maximizing continuation region can shrink considerably with volatility and this can lead to option value declining in volatility.

Figure 4 illustrates these effects with plots of the exercise boundaries and option values for various levels of stock return volatility. As volatility rises from 10% to 200%, the exercise boundary tends to fall first and then rise slightly. This is shown most clearly in Figure 4a, with risk aversion coefficient $A = 0.5$. The risk averse utility of the option payoff, as a function of the stock price, has both a convex region and a concave region, so in principle, an increase in volatility could either lead the executive to continue longer or exercise sooner. Apparently the concave portion dominates at low levels of volatility, making the executive exercise sooner as volatility rises. At higher levels of volatility, the convex portion seems to dominate and the boundary rises slightly. Empirically, Bettis, Bizjak, and Lemmon (2005) find that options are exercised earlier at higher volatility.
firms.

At the lower levels of risk aversion, as shown in Figures 4a and 4b, executive stock option value is generally increasing in volatility. However, at higher levels of risk aversion, as shown in Figures 4c and 4d, executive stock option value is decreasing in volatility at low levels of volatility. Here the negative effect on value of the drop in the boundary of offsets the positive effect of extreme stock prices becoming more likely. Marcus and Kulatilaka (1994) find a similar result.

4 General case with outside portfolio choice

This section examines the general problem with nontrivial outside portfolio optimization described in Section 2. Allowing for optimal investment of outside wealth in the market, the value function is now a function of both the stock price and outside wealth. In the continuation region, \( f(W, S, t) \) satisfies \( E(df) = 0 \). If \( f \) is sufficiently smooth, then, by Itô's Lemma, it satisfies the p.d.e.

\[
f_t + f_W [rW + \pi^m(\mu - r)] + S f_S(\lambda - \delta) + \frac{1}{2} f_{WW}(\pi^m)^2 \sigma_m^2 + \frac{1}{2} f_{SS} \sigma^2 + S f_{WS} \pi^m \rho \sigma_m = 0,
\]

(36)

where, from the first-order condition, the optimal investment in the market, \( \pi^m \), is given by

\[
\pi^m = -\frac{(\mu - r)f_W - S \rho \sigma_m f_{WS}}{\sigma_m^2 f_{WW}}
\]

The option’s market value, \( P(W, S, t) \) satisfies the p.d.e.

\[
P_t + Wr P_W + SP_S(r - \delta) + \frac{1}{2} P_{WW}(\pi^m)^2 \sigma_m^2 + \frac{1}{2} P_{SS} \sigma^2 + S P_{WS} \pi^m \rho \sigma_m - rP = 0,
\]

(37)

subject to the exercise policy determined in solving for \( f \). Assuming constant relative risk aversion, we solve Equations (36) and (37) simultaneously using an explicit finite difference method. To enforce stability, it is necessary to place a bound on the magnitude of the weight on the market in the outside portfolio in order to bound the portfolio volatility. When outside wealth is large relative to option wealth, that constraint is not binding,
but the constraint impacts the results when outside wealth is small. The constraint is potentially relevant empirically because it corresponds to constraints on borrowing and short-selling.

Unreported results suggest that the wealth, risk aversion, and volatility effects from the last section still hold in the presence of optimal trading in a market portfolio with a nonzero risk premium and correlation with the stock return. In particular, option value is still increasing with executive wealth, decreasing with executive risk aversion, and potentially non-monotonic with respect to stock return volatility. In addition, the optimal exercise policy appears to be characterized by a critical stock price for each possible date and wealth level, above which it is optimal to exercise and below which it is optimal to continue. We also note that when the market risk premium and the stock return correlation with the market are set to zero, then optimal market portfolio weight in the outside portfolio is zero, and the results are the same as those from the one-factor model of the last section.

The remainder of this section focuses on the dependence of the exercise policy and option value on the degree of correlation between the stock return and the return on the market. The results below disentangle the correlation effects from those of the portfolio constraint.

### 4.1 Correlation effects with zero market risk premium

Intuition suggests that when the market risk premium $\mu$ is zero, the only reason to hold a market position in the outside portfolio is to hedge the option position. Furthermore, all that should matter for the option exercise policy and value is the magnitude of the correlation, $\rho$, not the sign, since that is what determines how much stock risk can be hedged away.

Figures 5a and 5b confirm this intuition. Exercise boundaries and option values for a given value of $\rho$ are the same as for $-\rho$. To ease comparison with the last section, the figures show exercise boundaries across time for wealth equal to its initial value. The examples fix the riskless rate at 5%, the market return volatility at 20%, the stock return volatility at 50%, and the stock dividend at zero. The figures use the expression $\pi_{m} \equiv \pi_{m}/W$.

Figure 5a illustrates exercise boundaries and option values in the case that outside wealth is large relative to the option position. Initial wealth is six times the value of
shares under option, so that the portfolio constraint $|\pi^m/W| \leq 2$ is very loose. The level of executive risk aversion is also set high, $A = 10$, to make the amount of absolute risk aversion, $A/W$, comparable to that in some of the examples in the previous section. In this case, as the magnitude of correlation approaches one, the continuation region grows large and the option value approaches its maximized value, i.e., its Black-Scholes value. Indeed, if the executive can hedge the option position perfectly, there is no reason for a value-destroying early exercise.

Figure 5a also shows the effect of tightening the portfolio constraint to $|\pi^m/W| \leq 0.25$ or $|\pi^m/W| \leq 0.10$. Tightening the constraint uniformly reduces exercise boundaries and option values because it leaves the option holder exposed to more unwanted option risk. The impact of tightening the constraint is greater for larger correlation, because the larger the correlation, the larger market position the option holder would like to hold to hedge the option. Still, the effect of the portfolio constraint depends only on the magnitude of the correlation, not the sign. It has no impact when correlation is zero, because the optimal market position is zero in that case.

Figure 5b illustrates exercise boundaries and option values in the case that outside wealth is small relative to the option position. Here, initial wealth is 1.2 times the value of shares under option, which is the same as in the previous section in cases where terminal wealth is set equal to 2, and risk aversion $A = 2$. Because outside wealth is smaller relative to option wealth, relatively larger proportional market positions are necessary to hedge the option. Therefore, the portfolio constraint, $|\pi^m/W| \leq 2$, which was loose before, is tight here, and the exercise boundaries and option values are similar to those in the case of larger wealth but tighter portfolio constraint.

4.2 Correlation effects with nonzero market risk premium

When the market risk premium is positive, the executive would optimally choose a long position in the market in the absence of the option position. The risk premium on the stock is equal to its normal level, i.e., the stock’s market beta times the market risk premium. Thus the stock can be regarded as a portfolio containing the market and a risky idiosyncratic component that carries zero risk premium. Intuition suggests that in the absence of a constraint on the outside portfolio market weight, the executive will set the weight so as to hedge away the market component in the option position, and then incrementally increase the weight to the desired market exposure. In particular, at the op-
timum, the executive’s net exposure to the market and the idiosyncratic risk of the option position should depend only on the magnitude of the correlation, not the sign. Therefore, in the absence of a portfolio constraint, correlation effects on exercise boundaries and option values should be the same as in the case of zero market risk premium. That is, boundaries and option values should rise with the magnitude of correlation, independent of the sign, as more and more of the option risk can be hedged away, and the option value therefore approaches its maximized value.

Consistent with this intuition, the left plot of Figure 5c, in which wealth is high, shows that when the portfolio constraint is loose, $|\pi^m/W| \leq 2$, the correlation effects on option value are virtually the same as in the case of zero market risk premium depicted in Figure 5a. Now, however, the impact of tightening the portfolio constraint is not symmetric in $\rho$. It is still the case that tightening the constraint uniformly reduces boundaries and option values. But the effect is greater when the correlation is negative than when it is positive. There are two reasons for this. First, the natural net market position is positive, so the constraint leaves less room for the incremental long position needed for hedging when the correlation is negative than it leaves for the incremental short position needed for hedging when the correlation is positive. Second, the unhedged market risk inherent in the option position carries a negative risk premium when the correlation, and thus beta, is negative, while it carries a positive risk premium when the correlation is positive. The effect of the negative risk premium associated with negative correlation and unhedgeable market risk can ultimately outweigh the benefits of partially hedging, so that when the portfolio constraint is very tight, option value can even decrease as correlation falls from zero to minus one. This is illustrated in the left plot of Figure 5c for the case $|\pi^m/W| \leq 0.10$.

In the right plot of Figure 5c, outside wealth is lower relative to option wealth, which effectively makes the portfolio constraint $|\pi^m/W| \leq 2$ tighter. Thus, the correlation effect is comparable to that in the case of larger wealth but a tighter portfolio constraint. In particular, option value is now monotonically increasing in correlation, as in the case of initial wealth equal 6 and $|\pi^m/W| \leq 0.10$ shown in the left plot.

Figure 5d supports this reasoning by verifying that when the market risk premium is negative, the portfolio constraint is tighter for positive correlation. Indeed, the option values for a given $\rho$ when the market risk premium is $-8\%$ are exactly the same as for $-\rho$ when the risk premium is $8\%$.

To summarize, the results of this section suggest that in the absence of constraints on the outside portfolio weight in the market, option values and exercise boundaries
increase with the magnitude of the correlation between the stock return and the market return, independent of the sign of the correlation, and approach their levels under a value-maximizing policy. Imposing a bound on the magnitude of the market weight reduces boundaries and option values because it leaves the executive exposed to more option risk and thus precipitates earlier exercise. When the market risk premium is positive, the impact of the bound is greater for negative correlation than positive correlation, so much so that option value can change from a U-shaped function of correlation to a monotonic increasing function of correlation. This is because when the natural market position is positive, the bound places a tighter constraint on the incremental long position needed to hedge in the case of negative correlation than the constraint on the incremental short position needed for hedging when correlation is positive. Moreover, the unhedged market position in the option carries a negative risk premium when the stock beta is negative, making the option position even less tolerable. In the empirically relevant range with nonnegative market risk premium and nonnegative correlation between the stock return and the market return, we find that option value is unambiguously increasing in correlation.

5 The FASB approximation

In December 2004, the FASB issued SFAS 123(R), which requires firms to recognize option cost in earnings. The new standard requires firms to estimate option cost according to “established principles of financial economic theory” when market prices are unavailable. However, recognizing that full-blown estimation methods are still only beginning to develop, the FASB illustrates a variety of acceptable methods for approximating option cost, which include lattice methods and an adjusted Black-Scholes-Merton formula. The vast majority of firms use the latter method, which entails first estimating the option’s expected term (conditional on vesting) and then valuing the option at its Black-Scholes-Merton value using the option’s expected term in place of its contractual term. (This amount is then multiplied by the probability that the option vests, and later updated to reflect the actual number of pre-vesting forfeitures.) Equilar (2007) finds that 88% of Fortune 1000 firms used this method in 2006.

To see how the approximation works in the setting here, we compute the expected option term implied by the exercise policy of the executive in this model and then calculate the FASB approximation. The expectation of the option’s term is under the true
probability measure, as would be estimated using historical data on realized option lives according to the FASB guidelines. Table 1 presents expected terms, FASB approximations, exact option values, labeled ESO value, and approximation errors for a variety of parameterizations of the model. We start with two different base case parameterizations. The first is for a firm with high volatility, high beta, and low dividend rate, which might be typical of a young firm or a technology firm. The second is for a lower volatility, lower beta, higher dividend firm, such as a more seasoned firm in the industrial sector. Then we alternately vary the beta, the volatility, and the dividend rate of the base case firms, to show different effects in the cross-section. Throughout the examples, the risk free rate is 5%, the expected return on the market portfolio is 13%, and the volatility of the market return is 20%. The option vests at year 2 and expires at year 10. The executive’s coefficient of relative risk aversion is four and outside wealth is 0.6 times the grant date value of shares under option. This gives the options expected terms of about 5 years in the base cases, which is the average expected term used by Fortune 1000 firms from 2004 to 2006, according to Equilar (2007).

Panel A of Table 1 shows the effect of increasing the stock’s beta, or equivalently, its correlation with the market, since volatility is held constant in this panel. As explained in Section 4, increasing this correlation improves the executive’s ability to hedge option risk, which makes him willing to hold the option longer, i.e., raises the exercise boundary, and this increases the option’s present value. The columns labeled ESO value show option values increasing as beta increases from zero to 1.4. On the other hand, there are conflicting effects on the option expected term. On one hand, raising the boundary should increase the option expected term. On the other hand, when beta increases, the expected return on the stock rises commensurately, which reduces the time to reach the boundary. For the first base case, the latter effect dominates, and option expected life and the FASB approximation decline as beta rises, moving in the opposite direction as the ESO value. In the second case, the expected term is U-shaped in beta, but the approximation error still decreases in algebraic value monotonically.

Panels B and C of Table 1 show the effects of changing stock return volatility. Panel B shows the effect with beta held constant, in which case only the idiosyncratic component of the stock risk is varying. Panel C shows the effect with correlation held constant, in which case the idiosyncratic and hedgeable components of risk are held in constant proportion, such as in the case of an increase in leverage. Like the examples from Section 3, the ESO values are either increasing or U-shaped in volatility, as are the FASB approximations.
However, the FASB approximation rises faster with volatility, so the approximation error is increasing in algebraic value. The effect is less pronounced in Panel C for two reasons. First, in Panel C, some of the increase in risk is an increase in hedgeable risk, which has a positive effect on the exercise boundary and ESO value, because of the convexity of the option payoff, without the corresponding negative effect of increased net risk exposure. Second, in the FASB approximation in Panel C, there is the negative effect of increasing beta which increases the stock’s expected return and reduces the option’s expected term. Thus the approximation error increases more slowly in Panel C than in Panel B.

Finally, Panel D of Table 1 shows dividend effects. Both ESO values and FASB approximations decline as the dividend increases. However, expected option term actually increases with a higher dividend rate because it reduces the appreciation rate of the stock, so it takes longer to reach the exercise region. In the low end of the dividend range, the FASB value declines faster than the ESO value, so the approximation error decreases in algebraic value. As the dividend grows large, both the ESO value and FASB approximation converge to zero.

The effects illustrated here assume the executive follows the exercise policy determined by our model. Analyzing the actual FASB approximation errors that occur in practice requires knowing the actual exercise policies of executives, from which both correct option values and expected option terms could be estimated. Overall, the table suggests that FASB approximation errors can be small or large, positive or negative, depending on the firm profile.

6 The subjective option value discount

The focus of the paper is on the cost of the option to the firm, that is, the present value of the option payoff from the viewpoint of market participants who can trade freely. However, we can also use our framework to study the subjective value of the option from the viewpoint of the executive who cannot trade the option. The subjective option value is the amount of freely investable money that would give the executive the same utility as the option, as defined in Equation (8).

**Proposition 6** As long as the executive is free to buy the option, either explicitly or synthetically, the option’s subjective value cannot exceed its present value.
Proof If the executive were given an amount of cash equal to the option’s present value, the executive could always buy the option in the open market, so the executive could get at least as much utility as with the option itself. Therefore, the executive would need no more than the present value of the option, in the form of freely investable cash, to be as well off as with the option.

While Section 16-c of the Securities Exchange Act prohibits insiders from taking short positions in the stock, either directly or with option positions, there is no prohibition on long positions, so the result above should generally hold in practice and will certainly hold in the complete markets setting here. Violations of this inequality can arise if the executive is prevented from taking long stock or option positions in his outside portfolio. Bergman and Jenter (2007) make a similar argument, but reach a different conclusion about the feasibility of buying the nontransferable option in the market and thus leave open the possibility that employees will “overpay” for their options. However, it seems that if there is widespread demand for nontransferable options, there is nothing to prevent insurance companies and other financial institutions from competing with firms to offer employees this product, so employees will not have to overpay for them.

In Table 2 we use our model to quantify subjective option values and their discounts from present value for the same parameterizations shown in Table 1. The discount is defined as one minus the ratio of subjective value to present value. Panel A shows that, like present values, subjective option values increase with beta or correlation, and the discount declines. Intuitively, better hedging opportunities narrow the gap as the executive can effectively monetize more and more of the option’s value. Kahl, Liu, and Longstaff (2003) find a similar effect in the subjective value of restricted stock.

In Panel B, subjective option values are monotonically decreasing, and the discount is increasing, as the executive is exposed to more and more idiosyncratic risk. This is similar to the idiosyncratic risk effects in Kahl, Liu, and Longstaff (2003) and Henderson (2005). In Panel C, where correlation is held constant, subjective option value does not vary monotonically with volatility in the second base case. In this panel, in addition to the apparently negative effect of the increase in idiosyncratic risk, there is also the positive effect of an increase in market risk, which essentially increases the value of the tradeable component of the option payoff. Henderson (2005) finds a similar effect with a European option. In the second base case, this positive effect dominates at low volatility. The positive effect also operates on the exercise boundary and the option value, however, and the subjective value discount remains increasing in volatility.
Panel D illustrates dividend effects. Proposition 2 already established that increasing the dividend rate reduces the subjective option value. Panel D shows that in addition, the subjective discount is roughly constant at the low end of the dividend range. However, as the dividend grows large, both option cost and subjective value go to zero, and the discount appears to go to zero as the option becomes a smaller and smaller component of wealth.

The difference between the cost of the option to the firm and its subjective value to the employee is part of the cost of extracting better performance. In the language of the principal-agent literature, it is the cost of the inefficient risk allocation necessary to elicit unobservable or noncontractible effort. In addition to this, there is the cost of compensating the executive for the extra effort, which must be paid even if the effort is contractible and the extra compensation can be paid in cash. The results in Table 2 suggest that the total cost of elicit better performance may be quite high. On the other hand, evidence of positive stock price reactions to announcements of the adoption of an option plan in Brickley, Bhagat, and Lease (1985), DeFusco, Johnson, and Zorn (1990), Kato, Lemmon, Luo, and Schallheim (2005) and Langmann (2007) suggests that the market perceives the benefits to outweigh the costs.

7 Summary and conclusions

This paper advances the theory of executive stock option valuation with an in-depth study of the optimal exercise policy of a risk averse executive and its implications for option cost. Many recent valuation models for executive stock options set the exercise policy exogenously, assuming a single stock price boundary. This paper provides a simple example showing that the optimal exercise policy need not be of that form. However, when riskless bonds are the only investment available and the stock underlying the option appreciates at the riskless rate, we provide a sufficient condition for the existence of a single boundary. This condition is satisfied by constant relative risk averse utility functions with risk aversion coefficient less than or equal to one, and we find no counterexamples among our numerical results for constant relative risk averse utility functions with risk aversion coefficient greater than one.

We also prove that the executive exercises later and option cost is greater when he has less absolute risk aversion, or more wealth combined with decreasing absolute risk aversion. The exercise region is also larger, and subjective option value to the executive
is greater, the lower the dividend rate on the stock. All these monotonicity results hold regardless of the exact shape of the continuation region.

Numerical examples with constant relative risk averse utility show how the exercise boundary and option value vary with volatility. In contrast to results from standard option theory, or from executive stock option valuation models with a fixed exercise boundary, executive stock option value can decline in stock return volatility when increases in volatility cause the optimal exercise boundary to drop sufficiently.

Next, we show numerically how exercise boundaries, option cost, and option average life vary with stock beta and portfolio constraints when trading outside wealth in the market is possible. When the market risk premium and stock beta are nonnegative, option cost and average life increase with the stock beta and decreases as portfolio constraints are tightened. Option cost declines with the dividend payout rate and but average life actually increases because of the lower stock appreciation rate.

Finally, we examine the widely used approximation to option cost that is accepted by the FASB and find the approximation error can be small or large, positive or negative, depending on the firm’s beta, volatility, and dividend rate. In addition, we prove that the subjective option value from the executive’s viewpoint can be no greater than the option cost to shareholders and we show how the subjective discount varies with firm profile. Our results suggest that the cost of providing performance incentives is high and we conclude that the performance benefits must be quite significant.

Table 1
Option values and FASB approximations

Executive follows optimal option exercise policy and optimally invests outside wealth in market portfolio. Constant relative risk aversion coefficient is 4, outside wealth is 0.6 times value of underlying shares. Option is at the money and vests in 2 years. Initial stock price is normalized to one. Risk free rate is 5%. Market portfolio return has mean 13% and volatility 20%.

Table 2
Subjective option values and discount from firm cost
Executive follows optimal option exercise policy and optimally invests outside wealth in market portfolio. Constant relative risk averse aversion coefficient is 4, outside wealth is 0.6 times value of underlying shares. Option is at the money and vests in 2 years. Initial stock price is normalized to one. Risk free rate is 5%. Market portfolio return has mean 13% and volatility 20%.
