First Draft: May 2006
This Draft: January 2008
The monthly volatility of IPO initial returns is substantial, fluctuates dramatically over time, and is considerably larger during "hot" IPO markets. Consistent with IPO theory, the volatility of initial returns is higher among firms whose value is more difficult to estimate, i.e., among firms with higher information asymmetry. Our findings highlight underwriters' difficulty in valuing companies characterized by high uncertainty, and, as a result, raise serious questions about the efficacy of the traditional firm commitment underwritten IPO process. One implication of our results is that alternate mechanisms, such as auctions, may be beneficial, particularly for firms that value price discovery over the auxiliary services provided by underwriters.

Key words: IPO, Underpricing, Cycles, Information Asymmetry, Conditional Heteroskedasticity, Volatility

* We are indebted to Jay Ritter for the use of his data. We received valuable comments from Campbell Harvey (the editor), Harry DeAngelo, Craig Dunbar, Laura Field, Ravi Jagannathan, Jay Ritter, Ann Sherman, Ivo Welch, Donghang Zhang, Jerry Zimmerman, and two anonymous referees. We also received valuable comments from the participants in seminars at Boston College, Indiana University, Penn State University, the University of Arizona, the University of Rochester, the University of Southern California, the University of Toronto, and the University of Western Ontario, and from participants at the Duke-UNC Corporate Finance Conference and at the Harvard Business School Entrepreneurship, Venture Capital and Initial Public Offerings Conference. The views expressed herein are those of the authors and do not necessarily reflect the views of the National Bureau of Economic Research.

## 1. Introduction

Initial public offerings (IPOs) are underpriced on average: the secondary market trading price of the stock is on average much higher than the IPO price. A number of academic papers note that the equity in private companies with uncertain prospects is inherently difficult to value, and they posit that underpricing is an efficient response to the complexity of this valuation problem. ${ }^{1}$ In contrast, others have questioned whether the IPO price-setting process results in excess underpricing of IPO stocks.

This paper proposes a new metric for evaluating the pricing of IPOs in traditional firm commitment underwritten offerings: the volatility of initial returns to IPO stocks. We find that there is considerable volatility in initial returns. To the extent that the IPO price is a forecast of the secondary market price for the stock, these forecasts are not only biased downward (underpricing), but the range of the forecast (or pricing) errors is huge. While underpricing ${ }^{2}$ averages $22 \%$ between 1965 and 2005, a relatively small portion of offerings have underpricing that is close to this average: only about 5 percent of the initial returns are between $20 \%$ and $25 \%$. Moreover, nearly one-third of the initial returns are negative. The standard deviation of these initial returns over the 1965-2005 period is 55 percent.

If one considers IPO initial return volatility to be a metric for the difficulty of pricing IPOs, then one could reasonably expect this volatility to change over time with changes in the complexity of the pricing problem. Consistent with this intuition, we find that the volatility of initial returns fluctuates greatly over time. While prior literature has shown the existence of hot IPO markets characterized by extremely high initial returns (see, e.g., Ibbotson, Sindelar, and Ritter (1988, 1994)), we find that these hot markets are also characterized by an extraordinarily high variability of initial returns. That is, there is a strong positive correlation between the mean and the volatility of initial returns over time.

[^0]These descriptive statistics suggest that the level of uncertainty surrounding IPO firms and, correspondingly, underwriters' ability to value these firms, varies over time. The pricing of an IPO is a complex process. Although the issuer and its investment bank know considerably more about the firm's own prospects than any single market participant does, market participants as a whole know more than the firm about one critical input to the IPO pricing process: the aggregate demand for the firm's shares (see, e.g., Rock (1986)). Aggregate demand uncertainty is one of the principal problems facing issuers and their investment banks when attempting to price an IPO. By definition, the initiation of trading resolves this information asymmetry between the issuing firm and the market, i.e., trading resolves the firm's uncertainty about the market's aggregate demand. At this point, the information of all market participants becomes incorporated into the price.

Uncertainty about aggregate demand for IPO stocks varies in both the time series (it is higher at some points in time than others) and the cross section (it is higher for some types of firms than others). To understand these effects, we examine both variation in the types of firms going public and variation in market-wide conditions.

To the extent that the complexity of the pricing problem is greater for certain types of firms than others, one would expect greater pricing errors when the sample of firms going public contains a larger fraction of highly uncertain firms. A number of theories support this intuition and predict that an investment bank's pricing of an offering should be related to the level of information asymmetry surrounding the company. For example, Beatty and Ritter's (1986) extension of Rock (1986) predicts that companies characterized by higher information asymmetry will tend to be more underpriced on average, a prediction that has received considerable empirical support (see, e.g., Michaely and Shaw (1994)). As noted by Ritter (1984a) and Sherman and Titman (2001), information asymmetry should also affect the precision of the price-setting process. Specifically, it should be more difficult to precisely estimate the value of a firm that is characterized by high information asymmetry: firms with higher uncertainty should have a higher volatility of initial returns. Our results are consistent with these models: we find that IPO initial return variability is considerably higher when the fraction of difficult-to-value
companies going public (young, small, and technology firms) is higher. Given that these types of firms also have higher underpricing on average, this result is also consistent with the positive relation between the mean and volatility of underpricing noted above.

Our findings provide some evidence that the complexity of the pricing problem is also sensitive to market-wide conditions. Specifically, market-wide uncertainty related to IPO-type firms is higher during some periods than others, making it harder for underwriters and investors to accurately value IPOs. Our results on the importance of market conditions complement those of Pastor and Veronesi (2005) and Pastor, Taylor, and Veronesi (2007). Pastor and Veronesi analyze the importance of market-wide uncertainty on firms' decisions to go public. Conditional on going public, we find that similar factors also affect the pricing of the stock. ${ }^{3}$

The results in this paper suggest that the complexity of the pricing problem is related to both firm-specific and market-wide factors, and that this complexity limits underwriters' ability to accurately value IPOs. However, existing evidence suggests that price discovery is only one of a number of services provided by underwriters, and accurate price discovery may not always be underwriters' primary objective (see, e.g. Krigman, Shaw, and Womack (2001) and Houston, James, and Karceski (2006)). Yet even if price discovery is a secondary objective, it is difficult to conjecture why underwriters would deliberately overprice one-third of IPO offerings. Furthermore, it may be the case that other services obtained via the bookbuilding method (e.g., price support, analyst coverage, market making, placement of shares with long-term investors) can also be packaged with alternative price-discovery methods, such as IPO auctions, while also improving the accuracy of IPO price discovery.

Unlike traditional firm-commitment offerings, auctions incorporate the information of all market participants into the setting of the offer price. It is this knowledge of aggregate market demand that gives auctions an advantage over traditional firm-commitment offerings and potentially contributes to more

[^1]accurate pricing. In a preliminary analysis of a small sample of U.S. IPOs placed using an auction format, we find significant differences in the accuracy of price discovery during the IPO period (i.e., a significantly lower level and volatility of initial returns for auction IPOs) but little difference in the provision of auxiliary services (analyst coverage and market making) to issuers. The size of the U.S. auction IPO sample limits our power to draw strong conclusions about the relative advantages of the two IPO-placement methods available to issuers, but the evidence suggests that the efficacy of the pricesetting process cannot explain the dominance of the bookbuilding method for IPOs in the U.S. Perhaps many issuers place a very high value on underwriters' ability to guarantee certain post-IPO services, such as market making or analyst coverage. In fact, for some issuers, such services may be more important than the most accurate pricing at the time of the IPO, and, as suggested above, it may even be the case that underwriters are not striving to minimize pricing errors but rather placing more effort in the provision of these auxiliary services. However, other issuers, such as Google, are likely to obtain substantial analyst coverage, market making, etc., regardless of how they structure their IPO. Such issuers are likely to find an IPO auction to be the better alternative.

Our conclusions regarding the difficulty underwriters have in pricing IPOs in traditional firm commitment offerings are consistent with the findings of Derrien and Womack (2003) and Degeorge, Derrien, and Womack (2007) for the French market. However, to the best of our knowledge, there exists no evidence on this issue for the U.S. market. In contrast, there is a large literature on the accuracy of earnings forecasts, even though the earnings forecasting problem seems relatively easy compared with setting IPO prices, in the sense that the dispersion of forecast errors is much larger for IPO prices. ${ }^{4}$

Our results raise serious questions about the efficacy of the traditional firm commitment underwritten IPO process, in the sense that the volatility of the pricing errors reflected in initial IPO returns is extremely large, especially for certain types of firms and during "hot market" periods. The

[^2]patterns observed in the volatility of initial returns over time and across different types of issues illustrate underwriters' difficulty in valuing companies characterized by high uncertainty.

The remainder of this paper proceeds as follows. Section 2 analyzes the unconditional dispersion of IPO initial returns and the time-variation in the dispersion of IPO returns. Section 3 examines various firm- and deal-specific factors that are likely to influence initial IPO returns to see how much of the dispersion of IPO returns is attributable to the characteristics of the issuing firms. Section 4 investigates the influence of market conditions on initial return volatility, and Section 5 discusses other possible influences on the variation of initial returns. Based on our findings about initial return volatility, Section 6 presents some exploratory evidence on the ability of auction methods of placing IPOs to improve price discovery. Section 7 summarizes our results and presents concluding remarks.

## 2. IPO Return Data

### 2.1 Data Sources and Definitions

To assemble our dataset of IPOs between 1965 and 2005, we combine data from several sources. We begin with a sample of IPOs between 1965 and 1973 (excluding 1968) that were used by Downes and Heinkel (1982) and Ritter (1984b). ${ }^{5}$ We fill in data for 1968 by identifying company names and offer dates for IPOs listed in the Wall Street Journal Index and then collecting after-market prices from The Bank and Quotation Record. For the 1975-1984 period, we use Jay Ritter's (1991) hand-collected data. Finally, we use data from Securities Data Company (SDC) and from the Securities and Exchange Commission (S.E.C.) Registered Offering Statistics (ROS) database. We examine all of the offerings to ensure that none are double-counted because they were listed in multiple databases. In cases where offerings are in multiple databases (e.g., a 1980 IPO in the Ritter 1975-1984 database, the SDC database, and/or the ROS database), we rely first on hand-collected data, second on the SDC data, and last on the ROS data. Finally, from these samples we exclude unit IPOs, closed-end funds, real estate investment trusts (REITs), and American Depositary Receipts (ADRs).

[^3]As described in Table 1, these datasets provide us with a total of 11,734 offerings. For each offering we must obtain the initial return. For any IPO included in the Center for Research in Securities Prices (CRSP) database, we obtain the aftermarket price on the $21^{\text {st }}$ day of trading, and the initial return equals the percent difference between this aftermarket price and the offer price. For those IPOs not included in CRSP, we calculate the initial return using the closing price at the end of the first month of trading (as we do not have price data on the twenty-first trading day). To ensure that our results are not disproportionately affected by extremely small firms, our main analyses restrict the sample to firms with an offer price of at least \$5. After requiring that firms have both initial return data and an offer price of at least \$5, our dataset consists of 8,781 IPOs: 576 from the 1965-1973 Ritter data, 369 from the 1968 Wall Street Journal Index data, 1,199 from the 1975-1984 Ritter data, 17 from ROS, and 6,620 from SDC.

### 2.2 Descriptive Statistics

The first question we address is how best to measure the initial return to IPO investors or, equivalently, the pricing error realized by the issuing firm as measured by the percent difference between the IPO price and the subsequent secondary trading market price. Ruud (1993) and Hanley, Kumar, and Seguin (1993) find that underwriter price stabilization activities influence the trading prices of IPO stocks in the days immediately following the offering. Consistent with this, we find that $12 \%$ of the IPOs in our sample have a zero percent initial return - a far greater portion of the sample than would be expected in a random draw. To increase the probability that our measure of the aftermarket price is a true reflection of market value, we employ monthly (rather than daily) initial returns in all of our reported analyses. Consistent with price stabilization activities having subsided by this point, the proportion of monthly initial returns exactly equal to $0 \%$ is much smaller ( $4 \%$ of the sample) and there are substantially more negative initial returns.

Figure 1 shows the distribution of monthly initial returns to IPOs over a 41 -year time period. The 8,762 IPOs between 1965 and 2005 have an average monthly initial return of $22 \%$ and a large standard deviation of over $55 \%$. Figure 1 also shows a Normal distribution with the same mean and standard
deviation as this sample. In addition to having a high standard deviation, the initial return distribution is highly positively skewed and fat-tailed.

Lowry and Schwert $(2002,2004)$ and Loughran and Ritter (2004) note that the 1998-1999 period exhibits unusual dispersion of IPO returns. A closer inspection of the chronology of firms going public in 1998-2000 shows that the first very high IPO initial return is for eBay, which went public on September 24, 1998 (the one-day IPO return was $163 \%$ and the 21 -day return was $81 \%$ ). The end of the hot IPO market seems to have occurred in September 2000, as the number of IPOs fell to 21 from 59 in August, while the average IPO initial return fell to $33.1 \%$ from $66.2 \%$ in August. Thus, throughout the paper we define the IPO bubble period as September 1998 - August 2000.

Figure 1 also shows the summary statistics of IPO initial returns after omitting the IPOs that occurred during this IPO bubble period. The average IPO return omitting the bubble period is only $15 \%$, about two-thirds the size for the complete sample, and the standard deviation is also about one-third lower at $34 \%$. Both skewness and kurtosis are similarly much lower.

Figure 2 shows the monthly mean and standard deviation of IPO initial returns, as well as the number of IPOs per month, from 1965-2005. Both the level and the dispersion of IPO initial returns follow persistent cycles, with high average IPO initial returns and high standard deviations within a month occurring at roughly the same time. Ibbotson and Jaffe (1975), Ibbotson, Sindelar, and Ritter (1988, 1994), Lowry (2003), and Lowry and Schwert $(2002,2004)$ have noted this 'hot issues' phenomenon in the number of new issues per month and also in the average initial return per month, but the strong and similar pattern in the dispersion of initial returns is one of the contributions of this paper.

Table 2 contains the descriptive statistics underlying Figure 2. Each month we calculate the mean and standard deviation of initial returns for all IPOs during the month. ${ }^{6}$ Columns 2, 3, and 4 show the time-series mean, median, and standard deviation of these two monthly statistics. Column 5 shows the

[^4]correlation between the monthly mean and standard deviation. Finally, the last six columns show autocorrelations (up to six lags) of the initial return mean and standard deviation measures.

The cross-sectional standard deviation of IPO initial returns is about twice as large as the average IPO initial return, the two statistics are strongly positively correlated ( 0.864 in the 1965-2005 period), and the autocorrelations of the initial return dispersion are generally similar to those of the initial return mean. ${ }^{7}$ Table 2 also contains these same summary statistics for the 1965-1980, 1981-1990, and 19912005 subperiods, as well as for the 1991-2005 subperiod after excluding the September 1998-August 2000 IPO bubble period. Omitting the data from September 1998-August 2000 makes the remainder of the 1991-2005 period look very similar to the earlier sample periods in terms of the mean, dispersion, and autocorrelations of both initial return means and initial return standard deviations.

The evidence in Table 2 strongly suggests that the conditional distribution of IPO initial returns changes substantially over time, that some of these changes are predictable, and that the average initial return is strongly positively associated with the cross-sectional dispersion of IPO initial returns. This comovement in the mean and standard deviation, and the high standard deviation in months with lots of deals, are consistent with the fact that the initial return series is highly skewed, as seen in Figure 1. Our objective in this paper is to examine the economic factors that drive these statistical patterns. What causes the standard deviation of initial returns to be positively correlated with average initial returns, i.e., what causes the distribution of initial returns to be positively skewed? The subsequent sections of this paper examine these empirical patterns in greater detail, relating the dispersion of IPO initial returns to IPO market conditions, to the characteristics of the types of firms that go public at different points in time, and to secondary-market volatility.

[^5]
## 3. Why Are Average IPO Initial Returns and IPO Initial Return Volatility Related?

There is considerable variation in the types of firms that go public. Some firms are over 100 years old, are from well-established industries, and are broadly covered in the media before even filing an IPO. In contrast, other firms are less than one year old, are from new industries that are not wellunderstood by the market, and have received little or no media coverage prior to the IPO. Underwriters presumably find it more difficult to value firms about which the market's aggregate demand for shares is more uncertain, i.e., for which information asymmetry (as defined in Rock (1986)) is higher. Investment banks may overvalue some and drastically undervalue others, suggesting that the dispersion of underpricing across these types of firms will be quite substantial. In contrast, the greater amount of information available about more established firms should enable underwriters to more precisely estimate market demand for their shares and, therefore, more accurately value these companies, meaning the dispersion of initial returns across these firms will be relatively low.

The idea that the dispersion of initial returns would be related to the amount of information available about the firm was first suggested by Ritter (1984a), in an extension of Rock (1986) and Beatty and Ritter (1986). Specifically, Ritter (1984a) notes that IPO firms that are characterized by greater information asymmetry should have both greater average initial returns and a greater variability of initial returns.

Extending these ideas to a time-series context, clustering in the types of firms going public will cause time-series patterns in both the mean and the variability of initial returns. Suppose that during certain periods there is greater ex-ante information asymmetry about companies going public. We would expect initial returns during such periods to have a high mean (to compensate investors for the greater costs of becoming informed) and a high dispersion (because the underwriters will find it especially difficult to estimate the value of such issues). Consistent with these ideas, Figure 2 and Table 2 depict a positive relation between the mean and standard deviation. The remainder of this section more directly examines the extent to which the fluctuations in initial return volatility reflect underwriters’ ability to
value the type of firms going public at various points in time, i.e., during some periods a greater portion of the IPOs are relatively easy to value, while in other periods more of the firms are quite difficult to value.

Section 3.1 examines whether the average characteristics of firms going public each month are correlated with the mean and standard deviation of initial returns during the month. Section 3.2 investigates whether these characteristics contribute to the positive correlation between the mean and standard deviation of monthly initial IPO returns. Finally, section 3.3 directly examines the extent to which both the level and the uncertainty regarding individual firm initial returns are related to firmspecific sources of information asymmetry.

### 3.1 Descriptive Evidence

Our measures of firm- and offer-specific characteristics, which proxy for underwriters' ability to accurately estimate firm value, include:
(1) Rank is the underwriter rank, from Carter and Manaster (1990), as updated by Carter, Dark, and Singh (1998) and Loughran and Ritter (2004). If highly ranked underwriters are better able to estimate firm value, then we should observe a negative relation between rank and underpricing. However, Loughran and Ritter (2004) note that, in recent years, issuers' increased focus on analyst coverage rather than pricing implies that issuers may accept lower offer prices (i.e., greater underpricing) to obtain the best analyst coverage. Because the highly ranked underwriters tend to have the best analysts, this suggests a positive relation between underpricing and rank.
(2) $\log$ (Shares) equals the logarithm of the number of shares (in millions) offered in the IPO. Less information tends to be available about smaller offerings, suggesting that underwriters will have more difficultly valuing such issues.
(3) Tech equals one if the firm is in a high tech industry [biotech, computer equipment, electronics, communications, and general technology (as defined by SDC)], and zero otherwise. The value of technology firms tends to be much harder to estimate precisely.
(4) VC equals one if the firm received financing from venture capitalists prior to the IPO (as defined by SDC), and zero otherwise. If venture capitalists share information about the firm with underwriters, then underwriters may be better able to estimate firm value for such issues. ${ }^{8}$
(5) NASDAQ equals one if the IPO is listed on NASDAQ, and zero otherwise. Small, young, high-tech firms tend to list on NASDAQ, suggesting underwriters will find it more difficult to value these firms.
(6) NYSE equals one if the IPO is listed on the New York Stock Exchange, and zero otherwise. In contrast to NASDAQ, more established firms tend to go public on the NYSE, suggesting that underwriters will be better able to value these firms.
(7) $\quad \log ($ Firm Age $+\mathbf{1})$ equals the logarithm of (1 plus) the number of years since the firm was founded, measured at the time of the IPO. There is likely to be more uncertainty regarding the secondary-market pricing of the stocks of young firms. We use the Field-Ritter dataset of founding dates (see Field and Karpoff (2002) and Loughran and Ritter (2004)).
(8) |Price Update $\mid$ is the absolute value of the percentage change between the offer price and the middle of the range of prices in the prospectus. This represents a proxy for the amount of learning that occurs during the registration period when the IPO is first marketed to investors. Substantial learning (i.e., a higher absolute value of price update) is more likely for firms whose value is more uncertain.

Table 3 shows correlations between the monthly average characteristics of firms going public and the monthly means and standard deviations of initial returns. In the first two columns, correlations are computed using the full sample from 1981-2005, the period with sufficient IPO characteristic data from SDC. The final two columns contain the same correlations after omitting the IPO bubble period.

Months in which a greater proportion of firms are subject to higher levels of information asymmetry should exhibit both higher mean and a higher standard deviation of initial returns. Specifically, we expect initial returns to be high and more volatile in months when a lower fraction of

[^6]offerings is backed by venture capital, months when the average offering is smaller and by a younger firm, months when more companies list on NASDAQ rather than the NYSE, and months when the average absolute value of the price update is higher.

Consistent with our predictions, both average initial returns and the dispersion of initial returns are substantially higher in months when the firms offering stock are (on average) younger, and when a greater proportion of IPO firms are in high-tech industries. Also, months with more firms listing on NASDAQ tend to have a higher mean and standard deviation of initial returns, while months with more firms listing on the NYSE tend to have lower initial returns. To the extent that the absolute price update reflects the amount of learning that occurs during the registration period when the IPO is first marketed to investors, the strong positive correlations between this variable and both average initial returns and the dispersion of initial returns are similarly consistent with our predictions.

The positive correlation of the average and standard deviation of initial returns with underwriter rank suggests that issuers' focus on analyst coverage dominates any incremental skill that highly ranked underwriters have in accurately valuing companies - perhaps issuers' focus on analyst coverage rather than pricing leads highly ranked underwriters to exert less effort on accurately pricing the issue. Finally, the positive correlations of the average and standard deviation of initial returns with venture capital backing and shares offered are not consistent with our predictions. These positive correlations potentially indicate that companies backed by venture capitalists tend to be riskier and more uncertain. Thus, venture backing may be picking up a risky industry effect, rather than the effect of venture capitalists' incremental ability to decrease uncertainty. ${ }^{9}$

When the IPO bubble period is excluded from the sample, the correlations become smaller, and several are not reliably different from zero. Looking at the last two columns, the strongest effects are for the technology and firm age variables: months in which more firms are from high technology industries and months in which the average firm is younger exhibit a higher average and a higher standard deviation

[^7]of initial returns. In addition, the correlation between average underwriter rank and the standard deviation of IPO initial returns changes sign in this sub-sample, and the coefficient (although insignificant) is now consistent with highly ranked underwriters having more skill in valuing companies: months in which more IPO firms are advised by higher ranked advisors have lower variability of initial returns.

In sum, results in Table 3 provide suggestive evidence regarding the factors underlying the positive relation between the average and standard deviation of initial returns: when a greater fraction of the IPOs represent firms that are more difficult for underwriters to value, both average initial returns and the standard deviation of initial returns tend to be higher.

### 3.2 Regression Analysis

Evidence in the previous section indicates that the portion of firms that is especially difficult to value (for example because relatively little information is available) in a month contributes positively to both the mean and the standard deviation of initial returns in that month. This suggests that the positive correlation between the mean and standard deviation of monthly initial returns is driven, at least partly, by fluctuations in the types of firms going public over time. Tables 4 and 5 investigate this proposition more directly. Specifically, we first estimate the portion of initial returns that is attributable to firm- and offerspecific characteristics. For example, to the extent that young firms are more uncertain, we expect them to have higher initial returns - their expected initial return would be higher, ceteris paribus, than an older firm. Thus, we first obtain expected initial returns for each firm, conditional on various firm- and offerspecific characteristics. We then aggregate these expected initial returns by month, to investigate how much of the variation in initial returns over time reflects variation in the type of firm going public.

Table 4 shows the regressions used to obtain the expected initial returns. Specifically, we estimate cross-sectional regressions of initial returns on various firm- and offer-specific characteristics, where these characteristics are intended to proxy for the level of uncertainty regarding the secondarymarket pricing of the issue (and thus the uncertainty regarding the initial return). Table 4 shows several variants of the following regression:

$$
\begin{align*}
\mathrm{IR}_{\mathrm{i}}= & \beta_{0}+\beta_{1} \text { Rank }_{\mathrm{i}}+\beta_{2} \log \left(\text { Shares }_{\mathrm{i}}\right)+\beta_{3} \text { Tech }_{\mathrm{i}}+\beta_{4} \mathrm{VC}_{\mathrm{i}}+\beta_{5} \text { NYSE }_{\mathrm{i}}+\beta_{6} \text { NASDAQ }_{\mathrm{i}} \\
& +\beta_{7} \log \left(\text { Firm Age }_{\mathrm{i}}+1\right)+\beta_{8} \mid \text { Price Update }_{\mathrm{i}} \mid+\beta_{9} \text { Bubble }_{\mathrm{i}}+\varepsilon_{\mathrm{i}} . \tag{1}
\end{align*}
$$

IR is the IPO initial return, defined as the percent difference between the offer price and the closing price on the $21^{\text {st }}$ day of trading (as described in section 2.1). Bubble equals one if the IPO occurs between September 1998 and August 2000, and zero otherwise. All other variables are defined above.

As noted above, the primary purpose of the cross-sectional regressions shown in Table 4 is to identify firm and deal characteristics that are likely to be systematically related to initial returns so that we can aggregate the predictions and the prediction errors from these models (at the monthly level) to learn more about the role that information asymmetry plays in explaining the cycles in IPO initial return volatility. While these cross-sectional regressions have many potential statistical problems (for example, correlations in regression errors arising from the time clustering of IPOs), these problems are unlikely to bias the aggregation of fitted values and prediction errors.

Our objective in this table is to assess the importance of firm-specific measures of uncertainty, rather than the recent state of the IPO market. Consistent with this objective, the regression in column (1) of Table 4 includes only firm-specific measures (i.e., excluding the IPO bubble indicator variable). To examine the extent to which the extreme conditions during the IPO bubble of the late 1990s affect our regression estimates, columns (2) and (3) in Table 4 account for this period in two different ways. Column (2) includes an indicator variable that allows the average IPO return to be different between September 1998 and August 2000. Column (3) omits all of the observations between September 1998 and August 2000.

The regressions in Table 4 highlight the importance of the bubble period to the overall 1981-2005 sample. In column (2), the coefficient on the IPO bubble indicator variable implies that average IPO returns were $62 \%$ higher during these 24 months, holding other characteristics of the deals constant.

Moreover, in both columns (2) and (3), many of the coefficients on the firm- and deal-characteristic variables are different than those in column (1). This indicates that restricting coefficients on all explanatory variables to be constant throughout the entire sample period (including the IPO bubble period) causes misspecification and biased inferences, a conclusion that is consistent with the findings of Loughran and Ritter (2004) and Lowry and Schwert (2004). As a result, we focus on the regressions shown in columns (2) and (3).

Looking at column (2) of Table 4, results are broadly consistent with those reported in prior literature. Consistent with Loughran and Ritter (2002), Megginson and Weiss (1991), Lowry and Schwert (2004), Ritter (1991), and Beatty and Ritter (1986) we find that smaller offerings, technology firms, firms with venture capital backing, NASDAQ firms, and younger firms have the most underpricing. The positive coefficient on underwriter rank is inconsistent with Carter and Manaster's (1990) reputation hypothesis, but consistent with the findings of Cooney, Singh, Carter, and Dark (2001) and Loughran and Ritter (2004). We also find that firms listing on the NYSE have higher initial returns than firms listing on either Amex or the OTC, a result that is inconsistent with predictions. Finally, we find that the absolute value of the price update has a large, positive effect on the initial return. This is consistent with the effect of learning about unexpected investor demand during the book-building period. An absolute price update of $10 \%$ is associated with a $7.39 \%$ higher initial return $(t-s t a t i s t i c=7.32)$.

As mentioned above, the primary purpose of Table 4 is to obtain estimates of the ways in which firm- and deal-specific characteristics affect the pricing of each IPO. The fitted values from these regressions should represent the portion of initial returns that is attributable to underwriters' uncertainty regarding true firm value (e.g., Beatty and Ritter suggest that initial returns will be greater for highuncertainty issues). If the positive correlation between the monthly mean and standard deviation of initial returns is driven by clustering in the types of firms that underwriters can value more/less precisely, then we should observe similar correlations in the fitted values. To examine this, we aggregate at the monthly level the predicted and residual values of each observation from the Table 4 regressions. We then calculate the mean and standard deviation, across all IPOs in each month, of both these predicted and
residual values. Table 5 shows these means, standard deviations, and most importantly the correlations between the means and standard deviations across the raw data, fitted values, and residuals.

Specifically, in each of the three panels of Table 5, the first row represents the sample average of the monthly mean initial return measures (i.e., raw initial returns in the first column, predicted initial returns in the second column, and residual initial returns in the third column). The second row shows the sample average of the monthly standard deviations of the initial return measures. Finally, the third row shows the correlation between the mean and standard deviation, at the monthly interval.

Looking at the top panel in Table 5, we see that the fitted values from the column (2) regression in Table 4 (which employs the entire sample period and includes a dummy variable for the IPO bubble period) capture many of the features of the raw initial returns. Although the Table 4 regression only explains $24 \%$ of the variation in initial returns, the characteristics of the fitted values are similar to those of the raw data. Most importantly, the correlation between the mean and standard deviation of the fitted values is 0.63 , compared to 0.91 in the raw data. In contrast, the analogous correlation for the residuals is only 0.35 . Thus, the portion of initial returns that reflects the effects of information asymmetry (i.e, the fitted values from the Table 4 regression) drives much of the positive correlation between the mean and volatility over time. This finding is consistent our predictions, and with earlier literature suggesting that information asymmetry should affect both the level of the offer price and the precision of the price-setting process (see, e.g., Beatty and Ritter (1986), Ritter (1984), and Sherman and Titman (2001)). When the types of firms going public are especially difficult to value, both the mean and the variability of initial returns are relatively high. In contrast, when the types of firms going public are easier to value, both the mean and the variability of initial returns are substantially lower.

The second panel in Table 5 is similar, with the exception that the cross-sectional regression of initial returns is estimated on a rolling sample of the previous 500 IPOs. Specifically, we order the offerings in time, and separately estimate the cross-sectional regression of initial returns for each IPO (with the exception of the first 500 offerings on our sample) on the prior 500 IPOs. This estimation method allows coefficients to vary over time, thereby accounting more generally for the fact that the
influence of these variables on initial returns changes over time (see, e.g., Lowry and Schwert (2004)). After accounting for such fluctuations, the importance of information asymmetry as a determinant of the positive correlation between the mean and volatility of initial returns appears even stronger. The correlation between the mean and standard deviation of the fitted values is 0.84 , which is very close to the correlation of 0.92 observed in the raw data for the same sample period.

Finally, the last panel shows similar results after omitting the IPO bubble period. Due to the unique characteristics of this period, we want to ensure that results are robust to excluding it. While the correlation between the mean and standard deviation in the raw data is weaker ( 0.52 ), the predicted values from the cross-sectional regressions continue to explain a substantial portion of this relation (the correlation is 0.44 ).

In sum, certain IPOs are characterized by greater uncertainty, and it will be more difficult for underwriters to precisely estimate the value of such issues. In periods when a greater portion of issues is characterized by high uncertainty, underpricing should be higher on average and more dispersed. To empirically examine this conjecture, we isolate the portion of initial returns that reflects the effects of such uncertainty. Consistent with our predictions, our findings suggest that the strong patterns in both the mean and volatility of IPO initial returns reflect two phenomena: underwriters can more precisely value some types of firms than others, and the type of firms going public changes over time.

### 3.3 The Effects of Firm-specific Information Asymmetry on IPO Initial Return Dispersion

This section continues to examine the idea that issues characterized by greater uncertainty (i.e., issues that are more difficult for underwriters to value) will be characterized by higher average initial returns and a higher dispersion of initial returns. While the previous section provided strong support for this hypothesis in an aggregated time-series framework, this section tests the same concept on a firmspecific basis, by treating the sequence of IPOs in our sample period as a time-series process. As discussed earlier, many prior papers have employed cross-sectional regressions of initial returns on firmand offer-specific variables to show that the level of initial returns is positively related to measures of
information asymmetry. Table 6 increases our understanding of the pricing of IPOs by capturing not only the cross-sectional characteristics of initial returns, but also the time-series dynamics. Second, in addition to examining the determinants of the level of initial returns, our specifications enable us to also investigate the factors that affect the volatility of initial returns.

Treating this sample of IPO initial returns as the realization of a time series process is somewhat unusual, because the individual observations represent different firms. The observations are ordered so that they are sequential, but they are not equally spaced in calendar time. ${ }^{10}$ Nonetheless, the use of BoxJenkins (1976) ARMA models to account for residual autocorrelation and the use of Nelson's (1991) EGARCH models to account for residual heteroskedasticity allow us to substantially improve the statistical specification of our models. The EGARCH specification allows us to directly test whether our information asymmetry variables are related to both the level of and the variability of IPO initial returns in similar ways. ${ }^{11}$

Column (1) in Table 6 replicates the regression shown in column (1) of Table 4. As described above, this regression restricts the coefficient estimates to be the same across the entire 1981-2005 period. This serves as a baseline regression against which to compare the alternative specifications that capture the time-variation in both the level and the volatility of initial returns. Column (2) adds an ARMA(1,1) process to the baseline regression in column (1). The coefficient on the $\operatorname{AR}(1)$ term is close to 1 , and the MA term is slightly lower, but also highly significant. As discussed in Schwert (1987), ARMA(1,1) models similar to this occur frequently in financial and economic data, for example CPI inflation and measures of stock volatility. The relative magnitude of the AR and MA terms indicates that the residual autocorrelations are small but very persistent. After adding these time-series terms, the Ljung-Box (1979) Q-statistic, which measures the joint significance for the first 20 lags of the residual

[^8]autocorrelation function, drops from 4,318 to 64 , suggesting that the specification has improved dramatically.

While the ARMA terms control for autocorrelation in the level of initial returns, Figure 2 and Table 2 showed that there also exists strong cycles in the volatility of initial returns. Thus, for each regression we also calculate the Ljung-Box Q-statistic for the squared residuals, which is used to identify persistent residual heteroskedasticity. Not surprisingly, we find substantial time-varying heteroskedasticity (Q-statistic equals 1,194 , p-value $=0.000$ in column (2)). This implies the need for some form of autoregressive conditional heteroskedasticity (ARCH) model of the type introduced by Engle (1982).

To address this issue, column (3) adds an EGARCH(1,1) process to the ARMA(1,1) model in column (2). The first thing to note is that the coefficients on several of the explanatory variables change substantially. For example, underwriter rank, which was significantly positive in column (2), is now insignificantly different from zero. These changes are driven by the fact that the EGARCH specification essentially produces weighted least squares estimates, thereby reducing the influence of the IPO bubble period (which had very high variability). Thus, the estimates of the parameters of the regression model look more like the estimates in columns (2) or (3) of Table 4, which adjusted for the IPO bubble period by either adding a differential intercept (column (2)) or by completely omitting that data (column(3)). Finally, consistent with the patterns in raw initial returns shown in Figure 2, the EGARCH parameters indicate that the residual variance is very persistent (the GARCH parameter is 0.997).

Moreover, the asymmetric ARCH coefficient in column (3) is positive ( 0.029 , with an asymptotic t -statistic of 2.52 ), indicating that unusually large IPO initial returns are associated with a higher variability of subsequent residuals, while unusually low initial returns are associated with a lower variability of subsequent residuals. In light of the very persistent nature of both the level and variance of initial returns, this is broadly consistent with the strong positive correlation between the level and standard deviation of initial returns, as shown in Table 2. Notably, this contrasts sharply with what we have come to expect from studies of the variability of secondary-market returns, where positive shocks to
returns are followed by low volatility. Finally, the Ljung-Box Q-statistic for the squared residuals is much smaller in column (3), a value of 21, with a p-value of 0.257 , implying that most if not all of the conditional heteroskedasticity has been modeled adequately.

Column (4) of Table 6 adds the firm- and offer-specific variables to the $\operatorname{EGARCH}(1,1)$ process in column (3). This specification allows us to simultaneously examine whether these firm-specific factors affect both the level and variability of IPO initial returns, as suggested by our earlier evidence. As discussed above, prior literature has shown these factors to significantly affect the level of initial returns. Column (4) directly tests whether these same firm and offer characteristics are also significantly related to the variability of initial returns.

Consistent with our expectations, many of the proxies are significantly related to both the mean and the variance of initial returns in the predicted direction. For example, the coefficients on the Technology indicator variable imply that the level of the IPO initial return and also its variability are reliably larger for technology firms ( $t$-statistics of 2.22 and 4.45 , respectively). Venture-backed IPOs have marginally lower initial return variability ( $t$-statistic of -1.73 ), and firms with large absolute price updates (suggesting more learning during the book building process) have reliably larger IPO initial returns and variability of initial returns ( $t$-statistics of 5.39 and 5.02 ). Finally, consistent with older firms being subject to less information asymmetry, firm age is significantly negatively related to both the level of initial returns ( $t$-statistic of -3.28) and the dispersion of IPO initial returns ( $t$-statistic of -2.59).

The evidence presented here supports the conclusion that firm characteristics that one could naturally expect to be associated with greater uncertainty about the aftermarket price of the IPO stock are reliably associated with higher, and more variable, initial returns. Technology companies, companies not backed by a venture capitalist, young firms, and companies about which there is greater price discovery during the IPO registration period have significantly higher dispersion of initial returns than the remainder of the sample. Our tests are also more powerful than those offered previously in this literature: the combined ARMA/EGARCH models in Table 6 jointly model the time-dependence of the data that makes
the simpler statistical analysis typically used in the IPO literature problematic, particularly for any sample that includes the IPO bubble period.

## 4. The Relation between the Dispersion of IPO Initial Returns and Market Volatility

An additional factor that could explain the strong cycles in the dispersion of IPO returns is the well-known persistence in the volatility of secondary stock market returns. In particular, the peak in both the average level and the standard deviation of the initial returns to IPOs during the IPO bubble period is reminiscent of the high volatility of NASDAQ stock returns during this period (e.g., Schwert (2002)). It seems plausible that both underwriters and investors would have greater difficulty valuing IPO firms when the level of market-wide uncertainty about prices and value is especially high.

Figure 3a shows the implied volatility of the Standard \& Poor's composite index (VIX) and the NASDAQ composite index (VXN), both from the Chicago Board Options Exchange (CBOE), and there does seem to be a pronounced jump in market volatility in late August 1998. However, the biggest increases in market volatility on NASDAQ occurred starting in early 2000 and continued through the end of 2001. Figure 3b shows the ratio of these measures of volatility from 1995-2005. To the extent that the volatility of the NASDAQ index reflects uncertainty about the value of growth options, this ratio should mimic the uncertainty in IPO pricing. The September 1998-August 2000 period is identified by the dashed line in Figure 3b. It is clear from Figure 3b that market uncertainty about the value of NASDAQ stocks began to rise from a historically low level relative to S\&P volatility in September 1998 and it continued to rise throughout the IPO boom period. However, NASDAQ market volatility remained high until July 2002, long after the IPO market had been very quiet in terms of average initial returns, the volatility of initial returns, and the number of IPOs. Thus, this figure provides preliminary evidence that is inconsistent with the notion that secondary market volatility explains the volatility of IPO initial returns.

To more rigorously investigate the link between market-wide volatility and our measures of the monthly volatility of IPO initial returns, we first must determine the appropriate measure(s) of marketwide volatility. Monthly initial returns have both time-series and cross-sectional dimensions: the IPOs (by definition) are for different firms, implying a cross-sectional component, and the IPOs occur at different points in the month, implying a time-series component. Therefore, we examine market volatility measures computed in both the time-series and cross-section. The time-series metrics are the traditional monthly standard deviations of daily returns (e.g. Schwert (1989)), computed using equal-weighted portfolios of all firms on CRSP, and also for the sub-sample of firms listed on NASDAQ. ${ }^{12}$ The crosssection measures are the standard deviations of firm-specific monthly cumulative returns, again estimated using all firms on CRSP and for the sub-sample of firms listed on NASDAQ. ${ }^{13}$

These time-series and cross-sectional return volatility measures capture significantly different aspects of aggregate return variance. ${ }^{14}$ Time-series volatility measures, as traditionally employed in the literature on return volatility, reflect aggregate market return volatility - the extent of movements in stock indices within the month. On the other hand, our cross-sectional return dispersion measures capture aggregate firm-specific volatility - the extent to which firm-specific information flows cause stock prices to move in different directions, or change by different magnitudes, within the month (see, e.g., Bessembinder, Chan, and Seguin (1996) and Stivers (2003)). In this sense, the cross-sectional volatility measures reflect 'market-wide' firm-specific information flows: months with greater amounts of firmspecific news are characterized by greater cross-sectional return dispersion, while months in which most

[^9]of the news that moves stock prices is related to systematic factors affecting all firms are characterized by lower cross-sectional return dispersion.

Table 7 examines whether initial return volatility covaries with either of these measures of market volatility, where both initial return volatility and market volatility are measured at the monthly interval. The top panel shows significant correlations between the cross-sectional volatility measures and IPO initial return volatility. Correlations between IPO initial return volatility and the time-series market volatility measures are only significant when the market is restricted to the NASDAQ index, i.e., to firms that are more similar to the IPO firms. In sum, Panel A suggests that the dispersion in initial returns is related to market-wide volatility measures, in particular to firm-specific information flows and to the price movements of firms that are most similar to the IPO firms.

However, the bottom panel of Table 7 indicates that the importance of both cross-sectional and time-series volatility measures is driven by the IPO bubble period. ${ }^{15}$ Removing the bubble period from the sample reduces the correlations between IPO initial return volatility and both time-series and crosssectional measures of volatility considerably. Outside the bubble period we observe no significant positive correlations between IPO initial return volatility and measures of market volatility, with the only significant correlations being negative correlations between IPO initial return volatility and crosssectional dispersion of returns.

The lack of significant positive relations between market volatility measures and IPO initial return volatility during the majority of our sample period is somewhat surprising given the highly significant coefficients on the GARCH parameters in Table 6. These parameter estimates indicate substantial persistence in the IPO initial return volatility series that is not being captured by firm- and offer-specific characteristics. Intuitively, time-varying market conditions would seem a strong candidate

[^10]for a factor that might drive such persistence. Table 8 re-examines the importance of market conditions, in a multiple regression framework. Similar to Table 6, Table 8 shows an EGARCH specification, which models the determinants of both the level and the volatility of initial returns as a function of all the firmand offer-specific variables (from Table 6) plus the cross-sectional dispersion and time-series volatility of returns to the NASDAQ index. For each IPO, both the cross-sectional dispersion and the time-series volatility are defined over the 21 trading days prior to the offer date.

The results in Table 8 provide some evidence that NASDAQ time-series return volatility helps explain the volatility of IPO initial returns. However, the coefficients are only weakly significant, and introducing the volatility measures into the regression does not increase the explanatory power of the model (compared to the regression in column 4 of Table 6). We have also estimated regressions similar to those shown in Table 8 using measures of volatility that are more specific to IPO firms, for example the volatility of returns for portfolios of young firms only, small firms only, young and small firms only, etc. The results (not reported) are practically identical to those shown in Table 8. In sum, we conclude that while IPO initial returns volatility appears to be marginally affected by the secondary market volatility of returns, these effects are minimal when compared to the associations with variation in the types of firms going public.

Our examination of the relation between secondary market volatility and IPO initial return volatility relates to the findings of Pastor and Veronesi (2005). Pastor and Veronesi hypothesize that more firms choose to go public when market-wide ex ante uncertainty about the future profitability of young firms is high, as higher uncertainty increases the option value of going public. Pastor and Veronesi use the incremental return volatility (in excess of market return volatility) of recently completed IPOs as one proxy for ex ante uncertainty about future profitability. Extending the logic in our paper to Pastor and Veronesi's model, we would expect high ex ante uncertainty (about profitability) to flow through to high ex post variability of initial returns for the firms that choose to go public; if companies' decisions to go public are positively related to uncertainty (as Pastor and Veronesi find), then this uncertainty should also increase the difficulty that underwriters face when pricing the stocks of IPO firms and, therefore, the
extent of the pricing errors. The fact that IPO initial return volatility appears to be strongly positively correlated with IPO volume (Figure 2) provides some independent support for the Pastor and Veronesi model. However, our finding that changes in the type of firm going public has a much more substantial effect on the variability of IPO initial returns than changes in secondary market volatility indicates that the direct implication of the Pastor and Veronesi model can only partly explain IPO initial return variability. ${ }^{16}$

## 5. Other Factors that Might Affect Volatility of IPO Initial Returns

Prior literature in the IPO area includes a number of other models that relate to initial returns. While data limitations prevent us from examining each of these empirically, we briefly discuss several of these models. At the end of the section, we argue that these factors are not likely to be the primary drivers of the observed time-series patterns in initial returns.

Loughran and Ritter (2002) argue that prospect theory can explain part of the underpricing seen in IPO markets. In effect, equity owners who see their wealth increase due to large increases in the secondary market stock price after an IPO do not feel too bad about the fact that they could have raised more money in the IPO by setting a higher IPO price. Of course, unless the after-IPO market price of the stock is higher than it would be if the IPO had not been underpriced, there is no connection between the high value of the stock and the loss associated with underpricing, so prospect theory implies irrational behavior by the decision-makers of issuing firms.

Ljungqvist and Wilhelm (2003) argue that lower CEO ownership and smaller secondary components of IPOs in the late 1990s led to less sensitivity to IPO underpricing. They find some evidence that this factor explains part of the variation in underpricing in the 1999-2000 period. They also

[^11]argue that directed allocations of underpriced IPOs to "friends and family" led to a desire for underpricing by the executives of firms undergoing IPOs. ${ }^{17}$

Loughran and Ritter (2004) suggest that during the IPO bubble period many issuers had objective functions that focused on things other than maximizing the proceeds from the IPO. In particular, they argue that decision-makers in the issuing firms sought pay-offs from investment bankers in the form of allocations in the underpriced IPOs of other firms ("spinning"), so when their own firm went public they accepted underpricing as part of the quid pro quo exchange for the private benefits they received as investors in the underpriced IPOs of other firms. They also argue that issuing firms became very interested in coverage of their firms by securities analysts during this period, and perceived that an underpriced IPO would provide incentives for the underwriting firms to provide such analyst coverage.

We have been unable to find data that would allow us to directly test whether these supply-related factors can explain the level and variability of underpricing over longer sample periods before and after the IPO bubble period. While many hypotheses have been proposed for the unusual underpricing behavior during the 1998-2000 period, as shown in Figure 2, there have been several other hot issues episodes in the IPO market before 1998, and most of the institutional factors that have been identified as being unusual in the 1998-2000 period were not present in the earlier episodes (to the best of our knowledge).

[^12]
## 6. Implications of the High Volatility of IPO Initial Returns

The evidence in this paper strongly suggests that the bookbuilding process (the conventional pricing mechanism for IPOs in the United States) has a difficult time setting IPO prices that come close to equating demand and supply. Across our 1965-2005 sample period, nearly one-third of IPOs have negative initial returns and another one-third have initial returns of $25 \%$ or more. This phenomenon is particularly pronounced in "hot issues" markets: the standard deviation of initial returns was $126 \%$ during the September 1998-August 2000 IPO bubble period, compared to $30 \%$ during the remainder of our sample period.

At least a portion of this volatility in initial returns is driven by underwriters' tendency to incorporate only a portion of the information learned during the bookbuilding period into the final offer price. While there is much evidence (e.g., Hanley (1993), and recently Lowry and Schwert (2004)) that price updates that occur during the bookbuilding period reflect some information about demand, there is also much evidence that underwriters and/or issuing firms are reluctant to adjust the IPO price upward sufficiently when they learn that there is substantial excess demand at the proposed IPO price. In fact, the results in this paper suggest that IPOs in which underwriters revised the price by greater amounts (regardless of whether the revision was positive or negative) have larger pricing errors (as reflected in higher volatility of initial returns).

From the underwriters' perspective, it is arguably easy to see that a proposed IPO price is too low if the indications of interest are many multiples of the shares for sale in the IPO. However, it may be difficult to estimate the market-clearing price (i.e., the price that would equate the supply of shares for sale with demand) if one only observes excess demand at the proposed IPO price. Even if underwriters can confidently predict a "large" price increase after the IPO, they may remain quite uncertain about what the actual secondary market price will be.

In recent years, auctions have emerged as an alternative to the conventional bookbuilding process for the pricing and distribution of shares in IPOs. In contrast to bookbuilding methods, auction methods
allow the overall market to determine the price at which demand equals supply. Because information from all market participants is used to set the offer price in auctions, there is little reason to expect large price changes or high trading volume in the secondary market for auction IPO stocks.

Derrien and Womack (2003) and Degeorge, Derrien, and Womack (2007) compare the pricing of auction versus firm-commitment offerings in the French market and conclude that auctions are much better at identifying an IPO price that is close to the subsequent secondary market price. Consistent with our conclusions, they find that bookbuilding is at the biggest disadvantage during "hot issues" markets, when underpricing is largest and most uncertain. Nevertheless, they confirm the conclusions of Jagannathan and Sherman (2006) that the market share of auction mechanisms has diminished, despite the apparent improvement in setting IPO prices.

While Derrien and Womack (2003) and Degeorge, Derrien, and Womack (2007) provide evidence on the price-setting process of various IPO methods in the French market, to the best of our knowledge no evidence exists on this issue for the U.S. Market. Moreover, institutional differences in the day on which the offer price is set in the various types of French offerings complicate interpretations of findings in these prior papers. ${ }^{18}$

Table 9 contains a sample of 16 auction IPOs in the U.S. that were managed (or co-managed) by W.R. Hambrecht \& Co. ${ }^{19}$ All the IPOs in this sample are for firms that went public in the $1999-2005$ time period and listed on the NASDAQ. It is important to note that many of the IPO auctions conducted by W.R. Hambrecht were "dirty" auctions, meaning their offer price was set below the market clearing

[^13]price. ${ }^{20}$ The fact that W.R. Hambrecht chooses to run their auctions in this manner is consistent with Sherman (2005) and Jagannathan and Sherman (2006), who argue that the optimal IPO auction would give the auctioneer discretion in setting the offer price. As an example, Andover.net chose to price its offer at $\$ 18.00$, considerably below the clearing price of $\$ 24.00$. While this does not explain all of the initial return for Andover (its one-day initial return was $252 \%$ ), the extent to which such practices are common throughout the sample potentially causes initial returns to be higher than they otherwise would be. With the notable exception of Google, the auctions are by small firms: the average total assets for these firms (excluding Google) is $\$ 79$ million, compared to average total assets of $\$ 854$ million for conventional IPOs over the same period.

However, comparing auction IPOs to the full sample of traditional IPOs can be deceiving, as there is likely to be a selection bias in the type of firm undertaking an auction IPO. Therefore, we create a matched sample of firm commitment IPOs over the 1999 - 2005 period by taking all firm commitment IPOs in the same 2 -digit SIC code as, and with IPO proceeds within $25 \%$ of, one of our auction IPO observations. We eliminate duplicate matches from this comparison sample, which is essentially equivalent to obtaining a matched sample by sampling from the pool of traditional firm commitment IPOs over the 1999 - 2005 period without replacement. This procedure results in a matched sample of 267 firm commitment IPOs from 1999-2005 that are comparable to one (or more) of the auction IPOs in Table 9. Comparative statistics for the matched firm commitment IPOs are contained in the bottom four rows of Table 9. ${ }^{21}$

Initial returns for auction IPOs look quite different than those for the matched sample of traditional IPOs. For example, initial returns for the majority of auction IPOs are not very large,

[^14]particularly given that many of these offerings occurred during the IPO bubble period, a time when traditional IPOs were underpriced by large amounts. Average first-day initial returns across all 16 auction IPOs equal $17.1 \%$ compared to an average of $55.3 \%$ for size- and industry-matched traditional IPOs over the same period. Looking at the auction initial returns, we observe that there is one extreme outlier: Andover.net had a first-day initial return of $252 \%$. Because the number of auctions is so small, this has a substantial effect on the sample statistics.

We therefore calculate average initial returns after excluding this one outlier from the auction sample, and, for consistency, also excluding a similar portion of outliers from the matched firm commitment IPO sample. ${ }^{22}$ After excluding outliers from both samples, average first-day initial returns are $1.5 \%$ for the auctions, compared to $50.9 \%$ for the matched traditional IPOs. In addition to being lower on average, initial returns of the auction IPOs also have considerably lower dispersion. After excluding Andover.net from the auction sample (and also removing outliers from the matched firm commitment IPO sample for consistency), the standard deviation of first-day initial returns for the auction sample is $10.1 \%$, compared to $62.6 \%$ for similar firm-commitment IPO offerings (same 2-digit SIC code industry with similar offer proceeds).

These same patterns are evident in first-month initial returns, which we rely on in this paper to circumvent the effects of immediate post-offer price support by IPO advisors. Both the average and the standard deviation of initial returns are substantially lower for auctions than for matched firm commitment IPOs. Unfortunately, the size of our auction sample limits our ability to employ more advanced statistical techniques. However, in an attempt to assess the robustness of our results, we use a propensity score approach (results not reported) to compare the underpricing of auction versus firmcommitment IPOs. The propensity score approach consists of a first-stage probit regression, in which the dependent variable is an indicator variable equal to one for auction IPOs and zero for firm-commitment IPOs and the independent variables include firm age, underwriter rank, a technology industry indicator

[^15]variable, shares offered, and time fixed effects. Auction IPOs are then matched to the most similar firmcommitment IPOs based on the fitted values from this first-stage probit. In the second stage OLS regression, initial returns for IPOs in this matched sample are regressed on an auction dummy. Consistent with results reported earlier, this approach provides weak evidence that auction IPOs have lower initial returns than firm-commitment IPOs on average.

While this evidence is somewhat preliminary due to the limited time series and small sample of auction IPOs, Table 9 suggests that auctions of IPO stock result in considerably more accurate pricing than the conventional bookbuilding approach for comparable offerings. Whether one focuses on first-day or first-month returns, auction IPOs are considerably less underpriced (in fact, not underpriced at all on average after excluding Andover.net) and result in initial returns with a substantially lower standard deviation. As an additional estimate of the difference between auctions and firm-commitment offerings, we add an auction dummy to the GARCH models shown in Table 8, where the auction dummy equals one for each of the 16 auctions, and zero otherwise. Consistent with the descriptive statistics shown in Table 9, the results (not shown in a table) suggest that auctions have significantly lower underpricing than the firm-commitment offerings. However, the coefficient on the auction dummy is not significant in the volatility equation. As before, given the small sample of auctions we interpret this evidence as suggestive of the benefits of auctions, but certainly not conclusive.

There are many things, in addition to the price-setting process, that differ between firmcommitment underwritten IPOs and IPOs that are sold through an auction process. For example, it is unlikely that the underwriter would provide price support services (effectively putting a bid order in at or slightly below the IPO price for a short period after the IPO) in an auction IPO. Also, since the underwriter has no real control over allocating underpriced IPO shares in an auction IPO, there is no opportunity for using IPO shares to provide benefits to selected investors. To the extent that conventional underwriters provide additional services, such as market-making or securities analysts’ reports that would not be economical on a stand-alone basis, some issuing firms might accept some level of underpricing as compensation for these follow-on services. On the other hand, for IPO firms that would attract an active
investor following anyway, and for which many market-making firms are likely to compete, there is no reason to think that it is necessary to make side-payments to the IPO underwriter to acquire these tie-in services. Many of the examples of IPOs with the largest initial returns are firms that would be attractive to market-makers and to security analysts regardless of the process used to set the IPO price.

In any event, the argument that firm commitment offerings are accompanied by the provision of auxiliary services, thereby justifying their higher and more volatile underpricing, relies on evidence that firm commitment offerings are actually associated with higher levels of the provision of the services in question. Table 9 provides descriptive statistics on two auxiliary services that are generally thought to be associated with firm commitment offerings: analyst following (the number of analysts providing a price recommendation within six months of listing) and the number of market makers (measured on the $21^{\text {st }}$ trading day following listing).

There is little evidence that those companies choosing to go public via the auction method are disadvantaged on either of these dimensions. Across all 16 auctions, the average number of analysts is 3.6, compared to 3.7 for size- and industry-matched firm commitment IPOs over the same time period. Moreover, the auctions actually have a higher average number of market makers in the after-market than the matched firm commitment offerings: 22.6 versus $17.6{ }^{23}$ Like the other numbers in Table 9, these comparisons are suggestive rather than conclusive. For example, if we eliminate Google from the auction sample, the average number of market makers is similar across the two groups (18.5 for auctions and 17.6 for comparable firm commitment offerings), but analyst following is greater for the matched firm commitment offerings (average of 2.0 for auctions, vs. 3.7 for matched firm commitment IPOs).

Our results provide little support for the idea that companies obtain non-price related benefits when they choose the firm commitment method of underwriting. While there are other services that underwriters provide, for example price support and discriminatory allocation, we do not have data to examine such issues. Certainly, we cannot rule out the relevance of such auxiliary services in a firm's

[^16]decision between the auction and firm-commitment form of going public. However, at a minimum, the extreme difficulties that underwriters appear to have in pricing IPOs suggests that many firms could benefit from improved price discovery by moving away from the traditional firm-commitment contract seen so often in the U.S.

## 7. Conclusion

This paper documents the monthly dispersion of IPO initial returns, and demonstrates that the volatility of initial returns is large on average and varies considerably over time. The dispersion of initial IPO returns each month has a strong positive correlation with average initial returns each month (underpricing) over the 1965-2005 period. This relation is stronger in data from the IPO bubble period (September 1998 to August 2000), but persistently positive across all sub-periods analyzed, and contrasts markedly with the negative correlation between the volatility and mean of secondary-market returns.

The large and time-varying volatility of IPO initial returns documented in this study suggests that underwriters have great difficulty in accurately valuing the shares of companies going public through IPOs. The process of marketing an issue to institutional investors, for example during the road show, appears unable to resolve much of the uncertainty about aggregate market demand for the stock of IPO firms. If anything, we find the opposite: issues for which the most learning occurs during the registration period (large absolute price updates) also have higher volatility of initial returns (i.e. pricing errors). Furthermore, consistent with the notion that the complexity of the pricing problem in traditional firmcommitment offerings contributes to IPO initial return volatility, we report greater pricing errors (dispersion of initial returns) when a larger fraction of high information asymmetry firms (young, technology firms) goes public and during hot markets, particularly the IPO bubble of the late 1990s.

Our results raise serious questions about the efficacy of the firm-commitment underwritten IPO process, as the volatility of the pricing errors reflected in initial IPO returns is extremely large, especially for firms with high information asymmetry and during "hot market" periods. We conjecture that
alternative price-discovery mechanisms, such as auction methods, could result in much more accurate price discovery in the pre-trading period for IPO companies.

Fig. 1. Distribution of initial returns to IPO investments, defined as the percent difference between the aftermarket price on the $21^{\text {st }}$ day of trading and the offer price.

Mean and Standard Deviation of Initial Returns to IPOs and
the Number of IPOs by Month, 1965-2005

Fig. 2. Initial returns are defined as the percent difference between the aftermarket price on the $21^{\text {st }}$ day of trading and the offer price. Each month, the initial returns of each IPO during that month are calculated. The sample consists of IPOs with an offer price of at least $\$ 5$. The solid line represents average initial returns during the month, and the dotted line represents the standard deviation of these initial returns. The bars represent the number of IPOs per month (shown on the right Y-axis).

Each month, the mean and standard deviation of initial returns is measured across all firms that went public during that month. Initial returns are measured as the percent difference between the aftermarket price on the twenty-first day of trading and the offer price. Corr represents the correlation between the means and standard deviations through time. Months for which there is only one IPO yield an estimate of the mean IPO return, but not an estimate of the standard deviation. Months with three or more IPO's yield an estimate of the standard deviation.

## Table 3

## Correlations between the moments of IPO initial returns and IPO market characteristics (p-values in parentheses)

|  | 1981-2005 |  | 1981-2005 (omitting bubble) |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Average IPO <br> Initial Return | Std Dev of IPO <br> Initial Returns | Average IPO <br> Initial Return | Std Dev of IPO <br> Initial Returns |
| Average Underwriter Rank | 0.14 | 0.18 | -0.04 | -0.10 |
|  | $(0.010)$ | $(0.002)$ | $(0.755)$ | $(0.234)$ |

| Percent NYSE | -0.12 | -0.08 | -0.04 | 0.00 |
|  | $(0.017)$ | $(0.159)$ | $(0.699)$ | $(0.767)$ |
| Percent NASDAQ | 0.17 | 0.13 | 0.08 | 0.04 |
|  | $(0.000)$ | $(0.011)$ | $(0.236)$ | $(0.773)$ |
| Average Log(Firm Age +1$)$ | -0.29 | -0.33 | -0.11 | -0.27 |
|  | $(0.000)$ | $(0.000)$ | $(0.071)$ | $(0.000)$ |
| Average | 0.50 | 0.58 | 0.07 | 0.15 |
|  | $(0.000)$ | $(0.000)$ | $(0.256)$ | $(0.043)$ |

This shows correlations between the monthly average and standard deviation of IPO initial returns and monthly average IPO market characteristics. The sample consists of all IPO's with an offer price of at least $\$ 5$ that went public between 1981 and 2005. Initial returns are defined as the percent difference between the closing price on the twenty-first day of trading and the offer price. Underwriter Rank is the average Carter-Manaster (1990) underwriter ranking score, as updated by Carter, Dark, and Singh (1998) and Loughran and Ritter (2004). Log(Shares) is the logarithm of the number of shares (in millions) offered in the IPO. Percent Tech is the average of a Technology Dummy that equals one if the firm is in a high tech industry [biotech, computer equipment, electronics, communications, and general technology (as defined by SDC)], and zero otherwise. Percent Venture Capital is the average of a Venture Capital Dummy that equals one if the firm received financing from venture capitalists prior to the IPO (as defined by SDC)], and zero otherwise. Percent NYSE is the average of a NYSE Dummy that equals one if the IPO firm will be listed on the New York Stock Exchange, and zero otherwise. Percent NASDAQ is the average of a NASDAQ Dummy that equals one if the IPO firm will be listed on NASDAQ, and zero otherwise. Log(Firm Age+1) is the logarithm of the number of years since the firm was founded at the time of the IPO plus one. |Price Update| is the absolute value of the percentage change between middle of the range of prices in the initial registration statement and the offer price. The "bubble" period is defined to be between September 1998 and August 2000. The p-values, use White's (1980) heteroskedasticity-consistent standard errors.

## Table 4

## Relation between Initial Returns and Firm-Specific Proxies for Information Asymmetry

| Venture Capital Dummy | $(9.61)$ | $(5.13)$ | 0.012 |
|  | 0.037 | 0.041 | $(1.35)$ |
| NYSE Dummy | $(2.41)$ | $(2.84)$ | 0.059 |
| NASDAQ Dummy | 0.039 | 0.078 | $(2.33)$ |
| Log(Firm Age + 1) | $(1.31)$ | $(2.68)$ | 0.078 |
|  | 0.138 | 0.099 | $(3.3)$ |
| Price Update | $(5.16)$ | $(3.77)$ | -0.013 |
| Rubble Dummy (9/1998-8/2000) | -0.033 | -0.021 | $-(4.16)$ |
| Sample Size | $-(6.81)$ | $-(4.69)$ | 0.241 |

This shows cross-sectional regressions of IPO initial returns on firm- and offer-specific characteristics. The sample consists of all IPO’s with an offer price of at least $\$ 5$ that went public between 1981 and 2005. Underwriter Rank is the average Carter-Manaster (1990) underwriter ranking score, as updated by Carter, Dark, and Singh (1998) and Loughran and Ritter (2004). Log(Shares) is the logarithm of the number of shares (in millions) offered in the IPO. The Technology Dummy equals one if the firm is in a high tech industry [biotech, computer equipment, electronics, communications, and general technology (as defined by SDC)], and zero otherwise. The Venture Capital Dummy equals one if the firm received financing from venture capitalists prior to the IPO (as defined by SDC)], and zero otherwise. The NYSE Dummy equals one if the IPO firm will be listed on the New York Stock Exchange, and zero otherwise. The NASDAQ Dummy equals one if the IPO firm will be listed on NASDAQ, and zero otherwise. $\log$ (Firm Age +1 ) is the logarithm of the number of years since the firm was founded at the time of the IPO plus one. |Price Update| is the absolute value of the percentage change between middle of the range of prices in the initial registration statement and the offer price. Bubble equals one if the IPO occurs between September 1998 and August 2000, and zero otherwise. The t-statistics, in parentheses, use White's (1980) heteroskedasticity-consistent standard errors. $\mathrm{R}^{2}$ is the coefficient of determination, adjusted for degrees of freedom.

## Table 5

Monthly means and standard deviations of predicted and residual initial returns
1981-2005

|  | Whole Time Period: Column 2, Table 4 regression |  |  |
| :---: | :---: | :---: | :---: |
|  | Raw Data | Fitted Values | Residuals |
| Average Monthly Value | 0.20 | 0.20 | 0.00 |
| Std dev of values within each month, averaged across all months | 0.31 | 0.12 | 0.32 |
| Correlation between mean and standard deviation, monthly interval | 0.91 | 0.63 | 0.35 |
|  | Whole Time Period: Column 1, Table 4 regression estimated on Rolling Sample of the last 500 IPOs |  |  |
|  | Raw Data | Fitted Values | Residuals |
| Average Monthly Value | 0.20 | 0.21 | -0.01 |
| Std dev of values within each month, averaged across all months | 0.32 | 0.14 | 0.34 |
| Correlation between mean and standard deviation, monthly interval | 0.92 | 0.84 | 0.25 |
|  | Omitting Bubble Period (September 1998 - August 2000): Column 3, Table 4 regression |  |  |
|  | Raw Data | Fitted Values | Residuals |
| Average Monthly Value | 0.13 | 0.14 | -0.01 |
| Std dev of values within each month, averaged across all months | 0.24 | 0.05 | 0.24 |
| Correlation between mean and standard deviation, monthly interval | 0.52 | 0.44 | 0.44 |

To compute Average Monthly Value, we calculate the average initial return each month, and then average this value across all months. For the standard deviation, we compute the standard deviation of initial returns across all IPOs each month, and then average this value across all months. The correlation represents the correlation between this mean and standard deviation at the monthly interval. Fitted values and residuals come from regressions in Table 4. In the second panel, the regression is continuously re-estimated, based on the previous 500 observations.

| Sample Size | 6,840 | 6,839 | 6,839 | 6,839 |

This shows regressions of IPO initial returns on firm- and offer-specific characteristics. The sample consists of all IPO's with an offer price of at least $\$ 5$ that went public between 1981 and 2005, ordered by the date of the offer. The model in column (1) is the same as the model in column (1) of Table 4. Underwriter Rank is the average CarterManaster (1990) underwriter ranking score, as updated by Carter, Dark, and Singh (1998) and Loughran and Ritter (2004). Log(Shares) is the logarithm of the number of shares (in millions) offered in the IPO. The Technology Dummy equals one if the firm is in a high tech industry [biotech, computer equipment, electronics, communications, and general technology (as defined by SDC)], and zero otherwise. The Venture Capital Dummy equals one if the firm received financing from venture capitalists prior to the IPO (as defined by SDC)], and zero otherwise. The NYSE Dummy equals one if the IPO firm will be listed on the New York Stock Exchange, and zero otherwise. The NASDAQ Dummy equals one if the IPO firm will be listed on NASDAQ, and zero otherwise. $\log ($ Firm Age +1 ) is the logarithm of the number of years since the firm was founded at the time of the IPO plus one. |Price Update| is the absolute value of the percentage change between middle of the range of prices in the initial registration statement and the offer price. The $t$-statistics, in parentheses, use heteroskedasticity-consistent standard errors. The Ljung-Box (1979) Q-statistic is based on the first 20 lags of the residual autocorrelation function and has an asymptotic $\chi^{2}$ distribution under the hypothesis of no autocorrelation. For the EGARCH models in columns (3) and (4), the LjungBox Q-statistic is based on the autocorrelations of the standardized residuals. $\mathrm{R}^{2}$ is the coefficient of determination, adjusted for degrees of freedom.

The data are ordered according to the offer date of the IPO, but they are not equally spaced in time. The models in columns (2)-(4) estimate ARMA(1,1) models [Box and Jenkins(1976)] for the residuals from the model to correct for the autocorrelation of the residuals in column (1), as reflected in the lower Ljung-Box Q-statistics. The LjungBox Q-statistics for squared residuals suggest substantial autocorrelation of the conditional variance of the residuals, so the model in column (3) includes an $\operatorname{EGARCH}(1,1)$ model for the conditional variance of IPO returns. The model in column (4) also includes the information asymmetry variables that are in the return equation in the conditional variance equation, represented by the summation $\sum \mathrm{c}_{\mathrm{k}} \mathrm{X}_{\mathrm{kt} \text {. }}$

## Table 7

> Correlations between volatility of initial returns and the time-series and cross-sectional volatility of market indices
> (p-values in parentheses)

|  | Time-series <br> market volatility measure | Cross-sectional <br> market volatility measure |
| :--- | :---: | :---: |
| Market-wide Index, | 0.07 | 0.26 |
| January 1965 - | $(0.153)$ | $(0.002)$ |
| December 2005 |  |  |
| NASDAQ Index, | 0.17 | 0.25 |
| January 1973 - | $(0.009)$ | $(0.003)$ |
| December 2005 |  |  |

|  | Omitting September 1998 - August 2000 |  |
| :--- | :--- | :--- |
| Market-wide Index, | -0.00 | -0.11 |
| January 1965 - $(0.948)$ $(0.033)$ <br> December 2005   <br>    <br> NASDAQ Index, 0.05 -0.12 <br> January 1973 - $(0.400)$ $(0.036)$ <br> December 2005   |  |  |

Initial Returns are defined as the percent difference between the closing price on the twenty-first day of trading and the offer price. All IPOs between 1965 and 2005 with an offer price of at least $\$ 5$ are included in the sample. To compute monthly volatility, we compute the daily return on the given portfolio (market-wide index or NASDAQ index). We then calculate the standard deviation of daily portfolio returns for all days in the month. To compute monthly cross-sectional volatility, we compute the monthly return on each stock in the given portfolio (market-wide index or NASDAQ index). We then calculate the standard deviation of these monthly returns across all firms in the portfolio. All portfolios use equal-weights.

| Sample Size | 6,839 |  | 6,839 |  |

This shows regressions of IPO initial returns on firm- and offer-specific characteristics. The sample consists of all IPO's with an offer price of at least $\$ 5$ that went public between 1981 and 2005, ordered by the date of the offer. Underwriter Rank is the average Carter-Manaster (1990) underwriter ranking score, as updated by Carter, Dark, and Singh (1998) and Loughran and Ritter (2004). Log(Shares) is the logarithm of the number of shares (in millions) offered in the IPO. The Technology Dummy equals one if the firm is in a high tech industry [biotech, computer equipment, electronics, communications, and general technology (as defined by SDC)], and zero otherwise. The Venture Capital Dummy equals one if the firm received financing from venture capitalists prior to the IPO (as defined by SDC)], and zero otherwise. The NYSE Dummy equals one if the IPO firm will be listed on the New York Stock Exchange, and zero otherwise. The NASDAQ Dummy equals one if the IPO firm will be listed on NASDAQ, and zero otherwise. Log(Firm Age +1 ) is the logarithm of the number of years since the firm was founded at the time of the IPO plus one. |Price Update| is the absolute value of the percentage change between middle of the range of prices in the initial registration statement and the offer price. The variable $\mathrm{s}_{\mathrm{t}-1}^{2}$ is the timeseries variance of the returns to the equal-weighted portfolio of NASDAQ stocks from CRSP for the 21 trading days ending at day $\mathrm{t}-1$. The variable $\mathrm{c}_{\mathrm{t}-1}^{2}$ is the cross-sectional variance of the 21 -trading-day returns to stocks on NASDAQ ending at day $t-1$. The $t$-statistics, in parentheses, use heteroskedasticity-consistent standard errors. The Ljung-Box (1979) Q-statistic is based on the first 20 lags of the autocorrelation function of the standardized residuals and has an asymptotic $\chi^{2}$ distribution under the hypothesis of no autocorrelation. $\mathrm{R}^{2}$ is the coefficient of determination, adjusted for degrees of freedom.

The data are ordered according to the offer date of the IPO, but they are not equally spaced in time. The models include ARMA $(1,1)$ models [Box and Jenkins(1976)] for the residuals to correct for autocorrelation. The estimation also includes an $\operatorname{EGARCH}(1,1)$ model for the conditional variance of IPO returns, including as well the information asymmetry and market volatility variables that are in the return equation in the conditional variance equation, represented by the summation $\sum \mathrm{c}_{\mathrm{k}} \mathrm{X}_{\mathrm{kt} \text {. }}$

Table 9
Descriptive Statistics on U.S. Auction IPOs

| Name | Proceeds (\$m) | Issue date | Offer price | Number of analysts | Number of market makers | First-day initial return | First-month initial return |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Ravenswood Winery Inc | \$10.5 | 4/8/1999 | \$10.50 | 1 | 12 | 3.6\% | 0.6\% |
| Salon.com | 26.2 | 6/22/1999 | 10.50 | 1 | 15 | -4.8\% | 8.3\% |
| Andover.net Inc | 72.0 | 12/8/1999 | 18.00 | 2 | 17 | 252.1\% | 116.7\% |
| Nogatech Inc | 42.0 | 5/18/2000 | 12.00 | 2 | 17 | -21.6\% | -42.4\% |
| Peet's Coffee \& Tea | 26.4 | 1/25/2001 | 8.00 | 2 | 27 | 17.2\% | 6.3\% |
| Briazz Inc | 16.0 | 5/2/2001 | 8.00 | 0 | 18 | 0.4\% | -37.6\% |
| Overstock.com Inc | 39.0 | 5/29/2002 | 13.00 | 2 | 24 | 0.2\% | 3.8\% |
| RedEnvelope Inc | 30.8 | 9/24/2003 | 14.00 | 3 | 15 | 3.9\% | -4.0\% |

| New River Pharmaceuticals | 33.6 | 8/5/2004 | 8.00 | 3 | 15 | -6.3\% | -5.3\% |
| Google Inc | 1,666.4 | 8/18/2004 | 85.00 | 27 | 83 | 18.0\% | 34.1\% |
| BofI Holding Inc | 35.1 | 3/14/2005 | 11.50 | 1 | 20 | 0.0\% | -4.3\% |
| Morningstar Inc | 140.8 | 5/2/2005 | 18.50 | 1 | 28 | 8.4\% | 18.6\% |
| CryoCor Inc | 40.8 | 7/13/2005 | 11.00 | 3 | 21 | -1.2\% | -23.9\% |
| Avalon Pharmaceuticals Inc | 28.9 | 9/29/2005 | 10.50 | 3 | 17 | -9.6\% | -46.4\% |
| Dover Saddlery Inc | 27.5 | 11/17/2005 | 10.00 | 2 | 15 | 2.5\% | 0.0\% |
| Average | \$141.8 |  | \$16.09 | 3.6 | 22.6 | 17.1\% | 3.8\% |
| Standard deviation |  |  |  |  |  | 63.4\% | 38.6\% |
| Average excluding Andover.net |  |  |  |  |  | 1.5\% | -3.7\% |
| Std dev excluding Andover.net |  |  |  |  |  | 10.1\% | 25.0\% |
| Average for matched FC IPOs, 1999-2005 | \$65.0 |  | \$12.76 | 3.7 | 17.6 | 55.3\% | 75.8\% |
| Std dev for matched FC IPOs, 1999-2005 |  |  |  |  |  | 72.2\% | 114.0\% |
| Average for matched FC IPOs, 1999 - 2005, excluding outliers |  |  |  |  |  | 50.9\% | 66.3\% |
| Std dev for matched FC IPOs, 1999-2005, excluding outliers |  |  |  |  |  | 62.6\% | 86.3\% |

${ }^{*}$ This sample of auctions is from W.R. Hambrecht's OpenIPO process (http://www.wrhambrecht.com/comp/corpfin/completed recent.html), excluding Instinet (for which only a fraction of the IPO shares were sold in an auction format). The number of market makers is measured on the $21^{\text {st }}$ trading day following listing. The number of analysts represents those analysts providing a price recommendation within 6 months following listing. FC is firm-commitment.

[^0]:    ${ }^{1}$ See, e.g., Rock (1986), Beatty and Ritter (1986), Welch (1986), and Benveniste and Spindt (1989), among others.
    ${ }^{2}$ As discussed in more detail later, to avoid the effects of price support we measure initial returns as the percent change from the offer price to the closing price on the twenty-first day of trading.

[^1]:    ${ }^{3}$ Edelen and Kadlec (2005) find that market conditions also affect how aggressively issuers will price the offering. Their findings suggest that variation in issuers' pricing behavior in response to market conditions may also contribute to observed fluctuations in initial returns and/or the dispersion of initial returns over time.

[^2]:    ${ }^{4}$ For example, Gu and Wu (2003) find that the standard deviation of the errors in analysts' forecasts of quarterly earnings, scaled by the prior stock price, is 2.7 percent.

[^3]:    ${ }^{5}$ The original Downes and Heinkel (1982) data did not include information from 1968.

[^4]:    ${ }^{6}$ The standard deviation of initial returns is only calculated in months with at least three IPOs. As a result, in Table 2 the number of observations for mean initial returns (i.e., the number of months in which we can calculate this statistic) exceeds the number of observations for the standard deviation of initial returns.

[^5]:    ${ }^{7}$ The positive relation between average IPO returns and cross-sectional standard deviations within months partially explains the strong positive skewness and kurtosis shown in the frequency distribution in Fig. 1 (see, for example, Clark (1973)).

[^6]:    ${ }^{8}$ It is possible that companies backed by venture capitalists are characterized by greater information asymmetry than other companies. This would bias us against finding that venture-backed IPOs are valued more accurately and therefore have a lower variability of initial returns. Similarly, it is also possible that companies brought public by highly ranked underwriters are systematically different than those brought public by low ranked underwriters.

[^7]:    ${ }^{9}$ Similar dynamics potentially also affect the underwriter rank coefficient.

[^8]:    ${ }^{10}$ In cases where there are multiple IPOs on a single calendar day we randomly order the offerings.
    ${ }^{11}$ We use Eviews version 5.1 to estimate all of the ARMA and EGARCH models.

[^9]:    ${ }^{12}$ We experiment with value-weighted (by market capitalization) portfolios, but focus on the equal-weighted market portfolios since they are most comparable to our equal-weighted portfolios of IPO returns.
    ${ }^{13}$ To compute a time-series standard deviation for a given month, we determine the index returns on each day within a month, and then take the standard deviation across these daily index returns. In contrast, to compute a crosssectional standard deviation for a given month, we first determine the monthly return of each firm in the market, and then take the standard deviation across these N monthly returns.
    ${ }^{14}$ Our time-series and cross-sectional volatility measures are closely related to the disaggregated volatility measures in Campbell, Lettau, Malkiel, and Xu (2001) [CLMX]. Specifically, our time-series volatility measure is highly correlated with CLMX's market volatility component, and our cross-sectional measure is strongly related to CLMX's firm-specific volatility component.

[^10]:    ${ }^{15}$ This is consistent with the evidence in Schwert (2002), who shows that technology firms' volatility was unusually high during this period.

[^11]:    ${ }^{16}$ It is, of course, possible that market conditions also affect the type of firm going public (not just the decision to go public), suggesting that the coefficient on market volatility underestimates the true importance of market conditions for subsequent IPO initial return volatility. Alternatively, it may be that the volatility of secondary market returns is a poor proxy for ex ante uncertainty about future profitability (the key component in the Pastor and Veronesi model), even for segments of the secondary market that are most closely related to IPOs firms (e.g., the Nasdaq).

[^12]:    ${ }^{17}$ However, Lowry and Murphy (2007) suggest that the high levels of underpricing may lead more firms to adopt friends and family programs, rather than friends and family programs leading to more underpricing.

[^13]:    ${ }^{18}$ At least a portion of the difference between auctions and bookbuilding methods potentially reflects the fact that the offer price is set further in advance for offers using bookbuilding (see, for example, Jagannathan and Sherman, 2005).
    ${ }^{19}$ http://www.wrhambrecht.com/comp/corpfin/completed recent.html. This sample contains all auction IPOs managed by W.R. Hambrecht, with the exception of the Instinet IPO for which only a small fraction of the shares offered in the IPO ( 2.4 m out of 12.2 m ) were sold using the auction process.

[^14]:    ${ }^{20}$ W.R. Hambrecht states on its website that the issuing company and the underwriters take "a number of economic and business factors into account in addition to the clearing price. The company may choose to sell shares at the clearing price, or it may offer the shares at a lower offering price."
    ${ }^{21}$ We thank both anonymous referees for suggesting a matched-sample approach. Adding additional matching constraints, such as pre-IPO assets or sales reduces the size of the matching samples considerably, typically to below 100 observations. We employ the above matching criteria to preserve the size of the matched sample.

[^15]:    ${ }^{22}$ Specifically, we truncate the traditional IPO sample at the $3 \%$ and $97 \%$ levels. Excluding $6 \%$ of the traditional IPOs is approximately equivalent to excluding 1 out of 16 auctions ( $1 / 16=6.25 \%$ ).

[^16]:    ${ }^{23}$ All of the auction IPOs in Table 8 list on NASDAQ, and the number of market makers for the matched sample of traditional IPOs is available for NASDAQ-listed firm commitment IPOs only.
