Equilibrium Asset Pricing with Leverage and Default*

João F. Gomes† Lukas Schmid‡

February 2016

ABSTRACT

We develop a general equilibrium model linking the pricing of stocks and corporate bonds to endogenous movements in corporate leverage and aggregate volatility. Our equilibrium model with heterogeneous firms making optimal investment and financing decisions under uncertainty connects fluctuations in quantities and asset prices to movements in the cross-sectional distribution of firms. Countercyclical leverage drives predictable variation in risk premia, and debt-financed growth option exercise generates a high value premium. Endogenous default drives countercyclical credit spreads that are propagated into the real economy through their effects on investment. Endogenous leverage comes with higher and countercyclical aggregate volatility, producing large and skewed business cycles, with sharper, more pronounced, recessions.

1 Introduction

It is now well understood that leverage is a major driver of risk exposure and a key contributor to macroeconomic fluctuations. Leverage pushes many corporations to default in downturns often with substantial losses. In turn, expectations of those losses affect the pricing of corporate debt whose issuance aids successful financing of growth options and helps accelerating expansions. Debt-financed booms and debt-driven busts then contribute to aggregate volatility, and are reflected in asset returns, as the Great Recession of 2008-09 has reminded us. In spite of this, developing a framework suitable to study the joint determination of key corporate investment and leverage decisions of firms, aggregate volatility, and risk premia on stocks and corporate bonds has proved challenging.

This paper is an attempt to fill this gap. It presents a general equilibrium model with heterogeneous firms making optimal investment and financing decisions under uncertainty, and brings together many core insights from asset pricing, capital structure, and macroeconomics. Our model reconciles, in a unified framework, several core stylized facts about asset returns and many key features in macroeconomic aggregate and firm-level investment and financing variables. Specifically, we show that our model produces a sizable average equity premium and credit spread, together with plausibly low average returns on safe assets. It also implies that, in the time series, both price-dividend ratios and credit spreads have substantial predictive power for future stock returns, while generating a significant value premium in the cross-section of stock returns. A major contribution of our model is that it delivers an explicit connection between fluctuations in the cross-sectional distribution of firms and the time-series movements in macroeconomic aggregates and financial prices. In fact, this link is critical, as the mass of firms close to default, and hence the credit spread, becomes a key determinant of aggregate volatility and asset prices.

Endogenous movements in leverage contribute to the amplification and propagation of aggregate consumption risks and volatility. Debt-financed booms and busts amplify aggregate volatility, while accounting for a realistic long-term maturity structure of corporate debt significantly increases the persistence of fluctuations. This amplification raises the volatility of the market price of risk and produces quantitatively realistic risk premia. Importantly, endogenous default also increases the
volatility of consumption during recessions, as the mass of firms burdened by excessive leverage and closer to default grows. As a consequence, the equilibrium market price of risk also becomes sharply countercyclical.

Endogenous movements in leverage also explain much of our findings about predictability in both time-series and cross-section. Countercyclical leverage drives up risk premia on financial assets in downturns which, in the time series, is naturally reflected in both price-dividend ratios and credit spreads. Cross-sectionally, because investment is, at least partially, debt financed, value firms tend to have higher leverage ratios and these cross-sectional differences in leverage between growth and value firms amplify the dispersion in equity risk, and are a major driver of the value premium.

Some of these mechanisms are also shared by several partial equilibrium models of equity returns, even if leverage is exogenous and there are no financing frictions. In such models however, leverage affects assets’ conditional betas only through a direct cash flow effect which is often magnified by correlated, but exogenous, movements in discount rates. By contrast, in our general equilibrium setting, the main impact of leverage is felt indirectly though its general equilibrium impact on the stochastic discount factor. This is because fluctuations in leverage are endogenously linked to the dynamics of aggregate consumption. To be sure, in our model, both cash flow and discount rate effects are important and interact with each other. Nevertheless, it is the general equilibrium movements in consumption dynamics and the stochastic discount rate effect that arise as quantitatively more important determinants of asset return dynamics.

Because defaults tend to cluster in downturns, when the market price of risk is high, credit spreads will exhibit significant time-series variation that spills over into the real economy. In expansions, default risk and the market price of risk are low, so that debt-financed investment is cheap, while credit spreads spike up in recessions, due to rises in default rates and the credit risk premium. These endogenous movements in credit prices contribute to amplify the effects of shocks and generate more pronounced business cycle fluctuations. Much like in the data, credit spreads predict business cycles, providing an effective early warning for impending recessions. This is because the risk premium is very informative about the tail of the cross-sectional firm distribution

beyond aggregate productivity.²

A growing body of work has started to provide an integrated discussion of asset prices, leverage, and aggregate cycles in a modern setting, but our emphasis on risk premia is fairly unique. General equilibrium macro models used to explain the cyclical behavior of credit markets quantities and their correlation with macroeconomic aggregates largely abstract from variations in risk premia and asset prices.³ Unlike these classic financial accelerator papers, in our paper movements in credit spreads are mostly due to variations in credit risk premia and do not require large spikes in observed default events. In fact, in our model changes in risk premia drive about two thirds of the credit spread and also account for most of its predictive power.

There also a number of general equilibrium models with production and investment that exploit the role of asset prices and risk premia explicitly. However they all generally ignore the role of credit markets and credit risk.⁴ A parallel literature has also developed seeking to link credit risk to the financing decisions of firms and, more recently, with exogenous movements in risk premia and aggregate factors.⁵ Relative to these papers, our main contribution is to offer a more detailed general equilibrium model with production and explicitly link the movements in asset prices to endogenous changes in macroeconomic quantities.

Our work is also related to recent efforts to embed realistic credit markets into aggregate equilibrium models. Jermann and Quadrini (2010) show that credit shocks are necessary to generate the observed behavior of US economy. Their model is significantly different in that a firm can make intra period loans that are subject to stochastic collateral constraints and face adjustment costs to distributions. Brunnermeier and Sannikov (2010) build a continuous time macroeconomic model with a more detailed financial sector. Both of these models focus on a different set of

²Examples of the ability of credit spreads to forecast economic activity include studies by Keim and Stambaugh (1986), Schwert (1989), Stock and Watson (1991), Fama and French (1992), Lettau and Ludvigson (2004), Gilchrist and Zakrjasek (2008), and Mueller (2008). There is also a complementary literature documenting that asset prices more broadly have significant forecasting power for macroeconomic variables - see Ang, Piazzesi, Wei (2006) for a recent study and Stock and Watson (1999) for a classic contribution.

⁵Building on Leland (1994) recent quantitatively successful contributions include Hackbarth, Miao, Morellec (2006), Chen, Collin Dufresne, Goldstein (2008), Bhamra, Kuhn, and Strebualev (2008), Chen (201).
financial frictions and offer alternative institutional details. They both consider representative firm frameworks and largely abstract from variation in risk premia.\footnote{In addition Miao and Wang (2010) extend our framework to allow for endogenous labor supply, while Gourio (2010) introduces disaster risk in a simplified setting where firms are only alive for two periods. This ensures that firm heterogeneity plays no role in equilibrium and dramatically speeds up computation on the model.}

Methodologically, our approach shares some aspects with recent quantitative analysis of various aspects of the interactions between frictions at the corporate level, asset prices and macroeconomic fluctuations, and equilibrium asset pricing with heterogeneous firms.\footnote{Recent examples of the former include Bolton, Chen, Wang (2010), Hugonnier, Malamud, Morellec (2010), Eberly, Rebelo and Vincent (2010), Eberly and Wang (2010), and Ai, Croce, Li (2010). For the latter see Berk, Green and Naik (1999) and Gomes, Kogan, and Zhang (2003).}

The rest of the paper is organized as follows. Section 2 describes our general equilibrium model and some of its properties, while Section 3 discusses some of the issues associated with solving it numerically. A detailed discussion of our findings is provided in Section 4, before we conclude.

\section{The Model}

In this section we describe a general equilibrium with heterogeneous firms that are financed with both debt and equity. The model is designed to merge many key features of the investment and financing behavior of firms in a modern asset pricing setting.

Firms produce a unique final good that can be used for both consumption and investment. They own, and can add to, their capital stock by taking advantage of stochastic investment opportunities. Debt is used because of its tax benefits and because equity issues are costly. Hence the capital structure reflects combines the key elements of both modern trade off and pecking order theories. Both debt and equity can be issued regularly although there are issuance costs. Excessive debt may cause some firms to default. On the other hand, attractive business and credit conditions may also encourage new entrants to join in production.

Our detailed focus on credit and equity markets carries one cost in that we abstract entirely from labor market fluctuations. This is done only to maintain focus and preserve economic intuition. Adding a realistic labor market component that interacts meaningfully with the financial market conditions is a serious step, best taken separately.\footnote{Some recent papers include both credit frictions and labor markets, including for example Bernanke et al (1999),}
2.1 Firms

The production sector of the economy is made of a continuum of firms that differ in their productivity, size, and leverage, among other characteristics. In describing the problem of firms we take the stochastic discount factor for the economy as given. We show later how this is determined in general equilibrium by the optimal consumption and savings decisions of households. Nevertheless, it is important to recognize from the outset that a firm’s discount rates depend on the aggregate state of the economy, denoted $s$. As we will show, this includes both the current state of the aggregate shocks and the equilibrium cross-sectional distribution of firms.

2.1.1 Technology

All firms produce the same homogeneous final good that can be used for consumption or investment. The production function denoting the instantaneous flow of output is described by the expression:

$$y_{jt} = \exp(x_t + z_{jt})k_{jt}$$  \hspace{1cm} (1)

where $k_{jt}$ denotes the firm’s productive capacity and $x_t$ and $z_{jt}$ denote the values of aggregate and firm specific productivity, respectively. The behavior of these follows a first order autoregressive process with normal innovations:

$$x_t = (1 - \rho_x)\bar{x} + \rho_x x_{t-1} + \sigma_x v_{xt}$$  \hspace{1cm} (2)

$$z_{jt} = \rho_z z_{t-1} + \sigma_z v_{zjt}$$  \hspace{1cm} (3)

where $v_{xt}$ and $v_{zjt}$ are independently and identically distributed shock drawn from standard normal distributions. We use $N(x_{t+1}|x_t)$ and $N(z_{t+1}|z_t)$ to denote the conditional cumulative c.d.f of these two variables.

A growing literature has emphasized the importance of non-normal or disaster shocks and time

---

Jermann and Quadrini (2010) and, more recently, Khan and Thomas (2013). But none seeks to match the movements in equity and credit prices as well. Gilchrist et all (2011) matches credit spreads and macro quantities but is not interested in equity prices or the capital structure. On the other hand Gourio (2011) matches financial prices as well as we do but uses what is effectively a single firm model.
variation in volatility (e.g. Bloom (2009), Gourio (2010), Gilchrist et al (2011)). We choose not to include them to illustrate better how a detailed general equilibrium production model can generate endogenously the stochastic consumption volatility that is a key feature of several popular asset pricing models with exogenous consumption (e.g. Drechsler and Yaron (2010)).

2.1.2 Investment Opportunities

Each period firms have the opportunity to increase next period’s stock of capital \( k_{j,t+1} \). Investment takes place by adopting a new project of discrete size. Each adopted project costs, \( i \), goods per unit of capital, and it scales the stock of capital to \( k_{j,t+1} = g \times k_{jt} \). In other words, to increase next period’s stock of capital by a (net) factor of \( g - 1 \) the firm must surrender \( i_kk_{jt} \) units of current cash flow.\(^9\) It follows that only firms drawing investment costs below a cutoff value, \( \bar{i}_t \), will choose to increase their productive capacity.

Formally, we assume the cumulative distribution of investment costs, denoted \( H(i) \), is uniform and independent over time. Assuming \( Ei = g - 1 \) we can write the law of motion for a typical firm’s exiting stock of capital, \( k_t \), as:

\[
k_{j,t+1} = \begin{cases} 
k_{jt} & \text{with prob. } 1 - H(\bar{i}_t) 
gk_{jt} & \text{with prob. } H(\bar{i}_t) \end{cases}
\]

(4)

It follows that our model will produce an endogenous cross-sectional variation in firm size over time as firms optimally take advantage of differing investment opportunities. Finally, we assume all firms need to incur periodic maintenance costs, \( \delta k_{jt} \), akin to depreciation.

2.1.3 Firm Earnings and Financing

Firm’s can finance part of their spending through debt. We assume that this takes the form of a callable consol bond that pays a fixed coupon \( b_{jt}k_{jt} \) as long as the debt is not called or the firm does not default on its obligations.\(^10\)

\(^9\)The usual assumption is of course that \( i = g - 1 \) at all times. Here we generalize it to allow for the investment cost to be stochastic and differ across firms.

\(^10\)Defining the coupon as \( b_{jt}k_{jt} \) allows us to interpret \( b_{jt} \) as a measure of book leverage for the firm.
New debt can be issued in every period. To avoid dealing with multiple state variables at the same time however we assume that all existing debt is recalled at the same time. Without loss of generality we assume that debt is always recalled at market value, denoted $B(k, b, z, s)$. In words, this is the current value of a callable, defaultable, claim on a firm of size $k_{jt}$ with current idiosyncratic productivity $z_{jt}$, that promises to pay $b_{jt}k_{jt}$ per period, at a time when the aggregate state of the economy is given by $s_t$.

It follows that, except for gross investment expenditures, the after-tax cash flows to the firm’s equity holders, $\Pi(\cdot)$ are given by:

$$\Pi(k, b, b', z, s) = (1 - \tau)(\exp(x + z) - b - \delta)k + B(k, b', z, s) - (1 + \chi_b\kappa_b)B(k, b, z, s) \quad (5)$$

where we now drop subscripts and use the notation $b' = b_{j,t+1}$ and the indicator function $\chi_b$ takes the value of 1 when the firm changes its debt decision, i.e. $b' \neq b$. The variable $\kappa_b \geq 0$ captures transaction costs, such as underwriting fees, associated with calling and reissuing debt, while $\tau$ denotes the effective tax rate on profits adjusted for taxes on distributions and personal interest income. Finally, we assume firms can also fund themselves with new equity issues. Equity issues too are costly and we use $\kappa_e \geq 0$ to capture the unit costs associated with issuing any new equity.

### 2.1.4 Default and Debt Pricing

As discussed above, bondholders receive a periodic coupon payment as long as the firm does not default or recalled. If debt is called they pocket the current market value of the debt, $B(k, b, z, s)$. The only scenario under which they experience losses is upon default. Limited liability ensures that its is optimal for equity holders to default on their debt obligations whenever the equity value, denoted $V(b, z, s)$, becomes negative. Mathematically, this yields a default cutoff value for the idiosyncratic shock, $\bar{z}(b, x)$, such that the firm will default whenever $z < \bar{z}(b, s)$. Formally:

$$\bar{z}(k, b, s) = \min\{z : V(k, b, z, s) = 0\} \quad (6)$$

We show in the appendix that $\bar{z}$ is increasing in leverage $b$. 

8
If default occurs we assume that the firm’s assets (its capital plus current cash flows) are liquidated and the proceeds used to pay its creditors. A fraction \( \phi > 0 \) of these assets however is lost in liquidation so that creditors recover an amount equal to \((1 - \phi)(1 - \delta + xz)k\). Given these possibilities, the market value, \( B(k, b', z, s) \), of a claim promising to pay \( b' \) tomorrow, in a firm currently in state \((k, b, z, s)\), obeys the recursion:

\[
B(b', z, s) = EM(s, s') \left[ \int_{\bar{z}(b', s')} [b'k' + B(k', b', z', s')]dN(z'|z) + \int_{\bar{z}(b', s')} (1 - \phi)(1 - \delta + \exp(x' + z'))k'dN(z'|z) \right]
\]

(7)

where we take households/investors stochastic discount factor, \( M(s, s') \), as given for the moment.

Some basic properties of the market value of debt are established in the appendix.

Linearity of technology, investment and default costs in \( k \) implies that both equity and bond values are also linear in firm size, \( k \). It follows that the default threshold obeys \( \bar{z}(k, b, s) = \bar{z}(b, s) \).

Henceforth, we will simplify the notation and generally work with the normalized equity value function \( P(s, z, b) = V(s, z, b, k)/k \). Similarly, we will use \( Q(s, z, b) = B(s, z, b, k)/k \) denote the normalized market value of debt.

Equation (7) shows how changes in the recovery rate, \( \phi \), directly affect the relative price of credit to the firm. Thus changes in \( \phi \) act as effective shocks to credit supply, leading to tighter credit conditions and increases in credit spreads.\(^{11}\) To study the effect of financial shocks we also consider an expanded version of our model where we let \( \Gamma(\phi'|\phi) \) denote the conditional distribution of expected recovery rates \( \phi \).

\(^{11}\) Einsfelt and Rampini (2007) show these types of “liquidity” shocks can be important to explain measured variation in individual firm investment over time, while Jermann and Quadrini (2011) and Kahn and Thomas (2013) show how they can important to explain macroeconomic fluctuations.
2.1.5 Equity Value and Optimal Investment

We can now characterize the decisions of equity holders in detail. At every point in time the equity value (per unit of capital) obeys:

\[ P(b, z, s) = \max\{ P^0(b, z, s), P^I(b, z, s) \} \tag{8} \]

where \( P^I(b, z, s) \) denotes the equity value of a firm after it adjusts its stock of capital and \( P^0(b, z, s) \) denotes that of a firm that chooses not to invest at all. The inaction value, \( P^0(\cdot) \) is determined recursively by the Bellman equation:

\[ P^0(b, z, s) = \max\{ 0, \max_{b'} \{ \chi_e(1 + \kappa_e)\pi(b, b', z, s) + EM(s, s') \int_{z(b', s')} P(b', z', s')N(dz'|z) \} \} \tag{9} \]

Here \( \pi(\cdot) = \Pi(\cdot)/k \) and \( \chi_e \) is an indicator function that takes the value of 1 when the firm raises new equity and pays issuance costs \( \kappa_e \geq 0 \). The truncation in the continuation value reflects the impact of the possibility of default on the returns to equity holders. In turn the value of investing, \( P^I(\cdot) \) obeys:

\[ P^I(b, z, s) = \max\{ 0, \max_{b'} \{ \chi_e(1 + \kappa_e)(1 - \tau)(\exp(x + z) - b - \delta) - i + (1 + \chi_b\kappa_b)Q(b, z, s) + g.Q(b', z, s) + g.EM(s, s') \int_{z(b', s')} P(b', z', s')N(dz'|z) \} \} \tag{10} \]

It follows that there is an optimal investment cutoff that then obtained from:

\[ \bar{i}(b, z, s) = (g - 1) \left[ \max_{b'} \left\{ \frac{EM' \int_{z'} P(b', z', s')dz}{\chi_e(1 + \kappa_e)} + Q(b', z, s) \right\} \right] \tag{11} \]

When equity issuance costs, \( \kappa_e = 0 \), the term in square brackets is exactly Tobin’s average \( q \). It equals the expected value of all equity and debt claims on the firm, normalized by the value of the current stock of capital. In this case the optimal investment rule is imply that a firm will invest if and only if Tobin’s \( q \) exceeds \( i/(g - 1) \). For the marginal firm this is exactly 1, so that, at the aggregate level, this economy behaves very much like one with an aggregate investment technology.
exhibiting convex adjustment costs.

This concludes our description of the individual firm decisions. The appendix establishes a number of key properties about the relevant value and policy functions and Figures 1 and 2 illustrate them using the benchmark parameter values discussed below. Most of these properties are fairly intuitive. But it is worth noting that the investment cutoff \( \hat{\tau}(\cdot) \) is declining in the existing coupon payment \( b \), which means high leverage firms are less likely to invest - a "debt overhang" result.

Also important is the fact that if the discount factor \( M(\cdot) \) is constant the default cut-off \( \hat{\tau}(b, s) \) becomes linear in \( x \). In this case changes to aggregate productivity produce symmetric responses in the default cutoff and default rates over the business cycle.\(^{12}\) By contrast allowing for a significant role for risk premia, ties \( M(\cdot) \) to \( x \) and leads to asymmetric responses to aggregate shocks.

### 2.2 Aggregation

To characterize the general equilibrium of the model we must aggregate the optimal policies of each individual firm to construct macroeconomic quantities for our economy.

#### 2.2.1 Cross-Sectional Distribution of Firm

We begin by defining \( \mu_t = \mu(s) = \mu(b, z, x, \phi) \) as the cross-sectional distribution of firms over leverage, \( b \), and idiosyncratic productivity, \( z \), at the beginning of period \( t \), when the state of aggregate productivity is \( x \) and the recovery rate on assets in default \( \phi \).

Our timing is chosen so that that \( \mu(\cdot) \) is constructed before any current period decisions take place. As is well known this cross-sectional distribution will move over time in response to the aggregate state of the economy and will be the main computational obstacle to solving the model.

Given this distribution it is straightforward to define the total mass of firms at the beginning of the current period as:

\[
F(s) = F_t = \int d\mu_t
\]

Like \( \mu(s) \) itself, \( F(s) \) is constructed before individual firms’ decisions are made.

\(^{12}\)Popular examples are Bernanke et al (1997), Gertler and Karadi (2010).
Similarly, we can construct the equilibrium default rate in the economy as:

$$D(s) = 1 - \frac{\int_{z \geq \bar{z}(b,s)} d\mu}{F(s)} \quad (13)$$

Since the default threshold, $\bar{z}(b,s)$, is decreasing in $x$ this default rate will be countercyclical and, as discussed above, will generally respond asymmetrically to positive and negative shocks in $x$.

### 2.2.2 Firm Entry

Entry is necessary in the model to replace bankrupt firms and ensure a stationary distribution of firms in equilibrium. Accordingly, we assume that every period a mass of potential new entrants arrives in the economy. Potential entrants behave similarly to incumbents but face different initial conditions. Specifically, potential new entrants:

- have no initial capital, so that $k_{jt} = 0$, and thus begin production one period after entry;
- have no initial level of debt, so that $b_{jt} = 0$;
- draw an initial realization of the idiosyncratic shock, $z_{jt,t+1}$, from the long-run invariant distribution implied by (3), denoted $N^*(z')$;

Because they start with no capital, we assume entrants must make an initial investment of size $\alpha \bar{k}_t$, where:

$$\bar{k}_t = \frac{\int k_{jt} d\mu_t}{F_t} \quad (14)$$

denotes average firm size at time $t$. We will assume new firms start small so that $\alpha < 1$.

Like incumbents, entrants differ in the cost of this initial investment. For the sake of symmetry and parsimony we assume that the unit cost of their investment opportunities, $e$, is also drawn from the c.d.f. $H(e)$. As with incumbents, this implies that only firms drawing costs below the cutoff, $\bar{e}(z, s)$, find it optimal to invest and thus enter the market.
2.2.3 Aggregate Investment

Given the optimal behavior of individual firms, gross aggregate investment is equal to:

\[ I(s) = \int_0^{\tilde{\bar{i}}(s)} ikdH(i) + \int_0^{\tilde{\bar{e}}(s)} ekdH(e) - \int (1 - \chi)k d\mu + \int \delta k d\mu \]  

(15)

The first two terms sum the total investment costs of newly adopted projects, incurred by existing firms and by new entrants respectively. We then net out the disinvestment proceeds associated with asset liquidation by exiting firms. The last term adds the depreciation expenditures of all incumbent firms.

Since investment and default decisions are independent of \( k \) the law of large numbers implies that aggregate investment is given by:

\[ I(s) = K(s) \left[ \int_0^{\tilde{\bar{i}}(s)} idH(i)/F(s) + \int_0^{\tilde{\bar{e}}(s)} edH(e)/F(s) - D(s) + \delta \right] \]  

(16)

where \( K(s) = \int k d\mu(s) = \bar{k}(s)F(s) \) is the aggregate capital stock in the economy, when the aggregate state is \( s \).

Linearity of the aggregate production technology and these investment expenditures ensures that our economy will grow endogenously over time at a stochastic rate that is linked to average aggregate productivity \( x_t \). Faced with these aggregate shocks, our economy will exhibit persistent variation over time in the growth rates of output and consumption among others, providing a natural laboratory to investigate the effects of shocks to long run growth rates in a general equilibrium context with endogenous quantities and prices.\(^{13}\)

The expression for aggregate investment (15) integrates, in a parsimonious way, elements of rising marginal adjustment costs and partial irreversibility, both of which are important to generate quantitatively interesting behavior in asset prices. Because optimal investment cutoffs are increasing in productivity, the marginal cost of (aggregate) investment rises in good times, much

\(^{13}\)If the arrival of investment projects to new and old firms \( H(\cdot) \) is time varying, the model easily accommodates the type of investment specific technological shocks that have been emphasized recently in the literature (e.g. Greenwood, Hercowitz and Huffman (1988), Fisher (2006), Cummins and Violante (2007), Papanikolaou (2011) and Kogan and Papanikolaou (2013))
like it would in a simple aggregate model with standard convex adjustment costs (e.g. Jermann (1998)). And since bankruptcy is costly, investment becomes in effect only partially reversible, thus adding endogenous counter-cyclical variation to consumption growth in general equilibrium. This endogenously increases the market price of risk during recessions and exacerbates underlying variations in equilibrium asset prices.

2.2.4 Other Aggregate Quantities

Other aggregate quantities can be define straightforwardly. Aggregate output is given by:

\[ Y(s) = \int \exp(x + z)k \, d\mu = \exp(x)K(s) \]  

(17)

while the losses associated with bankruptcy are given by:

\[ \Phi(s) = \int (1 - \chi)\phi(1 + \exp(x + z))k \, d\mu \]  

(18)

Finally we can also construct the aggregate market value of corporate equity and debt respectively with the expressions:

\[ V(s) = \int Q(s, z, b)k \, d\mu \]  

(19)

and

\[ B(s) = \int B(s, z, b)k \, d\mu \]  

(20)

These definitions for the aggregate quantities make it clear that the aggregate state of our economy \( s \) is the triplet \( (x, \phi, \mu) \). All aggregate quantities and prices depend on the average state of productivity, financial conditions as well as the cross-sectional variation in firm productivities and leverage.

2.3 Households

To close our general equilibrium model we now describe the behavior and constraints faced by the households/investors. We assume that the economy is populated by a competitive representative
agent household, that derives utility from the consumption flow of the single consumption good, $C_t$. This representative household maximizes the discounted value of future utility flows, defined through the Epstein-Zin (1991) and Weil (1990) recursive function:

$$U_t = \{(1 - \beta)u(C_t)^{1-1/\sigma} + \beta E_t[U_{t+1}^{1-\gamma}]^{1/\kappa}\}^{1/(1-1/\sigma)}.$$ \hspace{1cm} (21)

The parameter $\beta \in (0, 1)$ is the household’s subjective discount factor and $\gamma > 0$ is the coefficient of relative risk aversion. The parameter $\sigma \geq 0$ denotes the elasticity of intertemporal substitution and $\kappa = (1 - \gamma)/(1 - 1/\sigma)$.

The household invests in shares of each existing firm as well as riskless bond which in zero net supply that earns a period rate of interest $r_t$. We also assume that there are no constraints on short sales or borrowing and that households receive the proceeds of corporate income taxes as a lump-sum rebate equal to:

$$T(s) = \tau \int \exp(x + z)k d\mu = \tau \exp(x)K(s)$$ \hspace{1cm} (22)

Given these assumptions the equilibrium stochastic discount factor that must be used to compare cash flows across two adjacent periods is defined by the expression:

$$M_{t,t+1} = \left[ \beta \left( \frac{C_{t+1}}{C_t} \right)^{-1/\sigma} R_{W,t+1}^{1-1/\kappa} \right]^\kappa.$$ \hspace{1cm} (23)

where

$$R_{W,t+1} = \frac{W_{t+1} + C_{t+1}}{W_t}.$$ \hspace{1cm} (24)

is the return on total household wealth, including bonds and tax proceeds.

As is well known, the absence of arbitrage implies that all gross asset returns in this economy will satisfy:

$$E_t[M_{t+1}R_{i,t+1}] = 1,$$ \hspace{1cm} (25)

15
for all assets \(i\), including the equity and bond investments in the firms described above.

### 2.4 General Equilibrium

Optimal investor behavior determines the equilibrium stochastic discount factor, \(M_{t,t+s}\), given household wealth. Earlier we described optimal firm behavior given the stochastic discount factor and shown how it determines aggregate investment and output as well as household wealth. Ensuring consistency between these two pieces of the economy requires that aggregate consumption by households is equal to aggregate production, net of investment and deadweight losses.

Formally our competitive equilibrium can then be constructed by imposing the additional consistency condition:

\[
C_t = C(s) = Y(s) - I(s) - \Phi(s)
\] (26)

This ensures that the stochastic discount factor used by each firm corresponds to that implied by optimal household behavior.\(^{14}\)

Finally we also need to specify a law of motion for the cross-sectional measure of firms over time. Given optimal firm policies this measure satisfies the following relation:

\[
\mu(z', b', x', \phi') = \text{Prob}(z_{t+1} < z', b_{t+1} < b', x_{t+1} < x', \phi_{t+1} < \phi')
\] (27)

\[
= \Gamma(\phi'|\phi)N(x'|x) \left[ \int \chi N(z'|z) \Omega_{b(z,b,x,\phi)=b'} d\mu(z,b,x,\phi) + N^{*}(z') \Omega_{b(0,0,x,\phi)=b'} \right]
\]

where \(\Omega\) is an indicator function that takes the value of 1 if the optimal policy function \(b(z,b,x,\phi)\) equals \(b'\) and 0 otherwise. \(N(\cdot), N^{*}(\cdot)\) and \(\Gamma(\cdot)\) are the cumulative distributions defined earlier.

The terms outside brackets in equation (27) capture the exogenous evolution in the aggregate states. The first term inside the brackets sums all the surviving firms which choose optimal leverage \(b'\) across all current states next period. The second term adds the mass of all entering firms that also choose optimal leverage equal to \(b'\). Recall that new firms arrive at the current period with \(z = b = 0\).

\(^{14}\)We follow the convention of considering that bankruptcy costs are deadweight losses but in a general equilibrium model this is a somewhat debatable choice, since some of these costs might be in the form of legal and accounting fees that accrue to other types of firms in the economy.
Figure 3 shows how the cross-sectional distribution changes after a long sequence of positive or negative shocks to aggregate productivity, $x$. Each panel depicts the equilibrium marginal distribution over debt commitments, $\mu(\cdot, b, \cdot, \cdot)$. This reflects both the effects of truncation by exit, refinancing and investment from incumbent firms, and the lumpy additions from new entrants. In expansions, most firms find it optimal to refinance at higher levels so as to fund the exercise of valuable growth options. Similarly, new entrants will be relatively highly levered, and these two effects combine to thin out the left tail of the distribution. During contractions however, many firms will find themselves burdened with excessive debt and optimally choose to default. At the same time, less attractive growth opportunities lead to fewer issues of new debt and to a larger concentration of low debt firms. Taken together, these effects will reduce the mass of firms at the right tail of the distribution. As we will show later, the predictive power of credit spreads comes from their ability to summarize the tail behavior of the cross-sectional distribution, $\mu(\cdot)$.

3 Computation and Calibration

This section offers a brief description of our approach to solve the model in section 2 and the choice of parameter values. As discussed above, the main obstacle to the computation of the competitive equilibrium is the fact that the cross-section measure of firms $\mu(\cdot)$ changes over time. In spite of this, and the level of detail in capturing firm behavior, our model remains relatively parsimonious and relies on relatively few independent parameters.

3.1 Computation

Computing the competitive equilibrium requires the following three basic steps:

- Given an initial stochastic discount factor $M_{t,t+s}$ solve the problem of each individual firms and determine the equilibrium level of entry and default

- Aggregate individual firm decisions and use the consistency condition (26) to compute aggregate consumption and wealth

- Ensure that the implied aggregate quantities are consistent with the initial process for $M_{t,t+s}$.
Convergence of this procedure delivers the equilibrium values for all individual and aggregate quantities in the model. Appendix 6 described this procedure in more detail.

3.2 Parameter Choices

In the benchmark model there are no credit market shocks and the recovery rate, $\phi$, does not move over time. This requires us to specify the value of fourteen parameters: three for preferences, seven for technology, and another four to capture institutional or policy features. Table 1 summarizes our choices.

The preference parameters are $\beta$, $\gamma$ and $\sigma$. They are chosen to ensure that the model matches the key properties of the risk free rate and the aggregate equity premium in the economy. Several studies have already shown how to combine time non-separable preferences and persistent shocks to aggregate growth to produce these results. More recent papers have expanded this analysis to general equilibrium models with all equity firms. Our parameter values are quite similar to several papers in this literature.\(^\text{15}\)

For the technology parameters we set the maintenance cost of capital $\delta$ to 2.1% per quarter, a value consistent with standard estimates of capital depreciation rates. Our choice of $\alpha$ is set to be consistent with relative size of new entrants, reported by Davis and Haltiwanger (1992). The size of growth options, $g$, is chosen to be consistent with the evidence on the lumpy nature of firm-level investment. In particular, we set it to match the empirical frequency of investment spikes of about 0.06 per quarter (Davis and Haltiwanger (1992)).

The volatility and persistence of the aggregate productivity process are set to $\rho_x = 0.96$ and $\sigma_x = 0.012$, largely in line with other macro studies and ensuring that we match the volatility and persistence of output growth in the data. The parameters for idiosyncratic shocks can be chosen to match a number of different moments of the cross-sectional distribution of firms. Since we are especially concerned with the role of default rates and credit spreads in our economy we set these parameters to match the unconditional means of both of these variables. This implies that $\rho_z = 0.92$ and $\sigma_z = 0.16$.

Finally, we need to specify a number of institutional parameters. The marginal corporate tax rate, $\tau$ is set to 20% to reflect the effect of of individual taxes on distributions and interest on the effective marginal tax rate. We choose the bankruptcy cost parameter, $\phi$ to generate average recoveries on defaulted bonds around 75% of face value (Warner (1977)). Formally, we set the value of $\phi$ so that in default:

$$\frac{(1 - \phi)(1 - \delta + \exp(x + z))}{B(s_0, b, z)} = 0.75$$ (28)

where $B(s_0, b, z)$ is the value of debt (relative to $k$) initially raised by the firm on average.

Finally, we determine equity and bond issuance costs, $\kappa_e$ and $\kappa_b$ to be consistent with stylized facts about firms’ issuing activity. Specifically, we set $\kappa_e$ to match the empirical frequency of equity issuances, while $\kappa_b$ determines the average effective maturity of corporate bonds, which we take to be five years.

For the version with credit market specific shocks, we assume that recovery rates in bankruptcy fluctuate over time, as a result of exogenous shocks to liquidation values. In this case, we assume that $\phi$ can take two values: a benchmark value of 0.25 reflecting average bankruptcy costs and an extreme (but rare) value of 0.75 that occurs during crisis. We also assume that $\phi$ evolves over time according to a two-state Markov chain with the following transition probabilities:

$$P[\phi_{t+1} = 0.25|\phi_t = 0.25] = 0.98,$$

$$P[\phi_{t+1} = 0.75|\phi_t = 0.75] = 0.5,$$ (30)

Thus periods of crisis are both rare and fairly temporary.

4 Findings

We begin describing our quantitative findings by summarizing the basic implications of our model for means and dynamics of major aggregate quantities and asset prices. We then examine the role of leverage and capital structure for these findings. Finally we discuss how the evolution of the cross-sectional distribution of firms over time becomes a determinant of economic cycles. In
particular we illustrate how movements in the cross-section amplify aggregate fluctuations and how credit spreads emerge as an indicator and predictor informative about these movements.

Most of our quantitative results are based on simulations. To construct the statistics reported below we solve the benchmark model and alternative specifications by numerical dynamic programming as detailed in Section 3. We then simulate the implied equilibrium policies at quarterly frequency to construct 1000 independent panels of 64 years each and report averages across all simulations. Unless otherwise noted we always report the relevant empirical moments for the sample period between 1951 and 2014.

4.1 Basic Properties of the Benchmark Model

Table 2 reports basic macroeconomic and financial moments from the benchmark model. We start by noting that the model is quantitatively consistent with salient features of US business cycles, as captured by the volatilities of consumption, output, and investment. Similarly, the share of investment (and hence consumption) is plausible and close to the actual data.

Moreover, both the level of the risk free rate and the equity premium are very close to those observed in the data, and this match does not require the very large movements in the risk free rate often associated with habit preferences. Essentially, this is because the persistent stochastic variation in growth rates generated by our model increases the household’s precautionary savings thereby lowering equilibrium interest rates.

While Bansal and Yaron (2004) have shown that accounting for long run movements in consumption and dividends, combined with preferences for a early resolution of uncertainty, delivers realistic risk premia in an endowment economy setting, this has proved harder to implement in general equilibrium production economies (Kaltenbrunner and Lochstoer (2010), Campanale, Castro and Clementi (2009), Croce(2010)). This is because in a production economy, general equilibrium restrictions often tie dividends very closely to consumption, while empirically, dividends are much more volatile than consumption. In our setup, however, financial leverage (endogenously) breaks the tight link between dividends and consumption and renders dividends an order of magnitude more volatile. This allows us to generate a more realistic amount of stock market volatility and is
crucial in matching the aggregate equity premia.\textsuperscript{16}

Table 2 also shows that our baseline calibration implies realistic levels of corporate leverage ratios, default rates and credit spreads (these statistics are based on the average properties of the cross-sectional distribution of firms). Plausibly low equilibrium leverage ratios reflect realistic pricing of corporate debt. As in recent work by Bhamra et al (2008) and Chen (2008), our success in matching credit market data relies on the fact that default occurs in periods of very high marginal utility, thereby significantly increasing the effective cost of default and the required compensation to bondholders. In our model, however, cash flow and discount rates are jointly endogenous determined.

Tying macroeconomic fluctuations to variation in default rates is then the key component of the large credit spreads and the reason we can match the data along this dimension. With a realistic default rate of 1.11\%, risk neutral valuation would imply a credit spread of, at most, 28 basis points.\textsuperscript{17} Instead, our calibration generates a credit spread of 108 basis points, much closer to the empirical counterpart. Unlike other popular macro models with credit markets, it is this credit risk premium, induced by the (endogenous) covariance between default rates and the market price of risk, and not default rates that account for the large credit spreads in our model.\textsuperscript{18}

Lastly, Table 2 documents that our heterogeneous firm economy also generates realistic cross-sectional dispersion in equity risk premia. More specifically, the model generates a spread between the returns on portfolios of the highest and the lowest decile of book-to-market sorted companies, that is, a value premium $E[r^v - r^g]$, in line with the empirical evidence. A quantitatively realistic value premium is broadly consistent with the literature modeling links between irreversible investment and asset returns (see e.g. Gomes et al (2003), Zhang (2005), Garleanu et al (2012)), much as we do. On the other hand, our approach differs from these models in that growth option exercise is linked to capital structure through debt financing. We explore the asset pricing implications of this added element of realism below.

\textsuperscript{16}Although we do not report these numbers here, the model also generates a slow moving pattern in leverage (Lemmon, Roberts and Zender (2008)) and the long run movements in aggregate dividends observed in the data (Bansal and Yaron (2004)).

\textsuperscript{17}Assuming a realistic recovery rate of about 75\% which our model is calibrated to match.

\textsuperscript{18}Our decomposition is also consistent with Elton, Gruber, Agrawal and Mann (2001) who estimate that about two thirds of the credit spreads are due to the credit risk premium.
4.2 Cyclical Patterns and Return Predictability

Risk premia on both stocks and corporate bonds reflect firms’ performance and policies across economic cycles, induced by stochastic variation in growth rates. Table 3 documents the cyclical behavior of several investment and financing variables by reporting their cross-correlations with GDP. Although all variables have the correct cyclical behavior the implied correlations are sometimes higher than in the data. Intuitively this is because without financing shocks, probably relies too much on a single source of aggregate uncertainty and innovations in output growth are too closely tied to those in aggregate productivity.

Persistence in productivity shocks implies a strongly pro-cyclical behavior in both aggregate investment and net entry as new firms enter the market and build up productive capacity in anticipation of higher future profits. As in the data, our firms are more likely to issue equity during good times in the model, although the correlation with economic activity is modest. This is because equity issues take place to both fund investment in good times and also to recapitalize the firm in bad times. Debt issues are also mildly procyclical, as in the data. A finding not reported in the table is the fact that the frequency of debt issuance is also procyclical, making effective debt maturity countercyclical. This is because firms are more likely to pay the transaction costs associated with refinancing in times of high profits.

Since market values of firms and price-dividend ratios are both strongly pro-cyclical, the model generates a realistic countercyclical pattern in market leverage. Elevated leverage in downturns renders both default rates and credit spreads strongly countercyclical since default becomes less attractive when profits are temporarily high. This endogenous comovement underlies the substantial credit risk premium embedded in the pricing of corporate bonds.

In our general equilibrium economy, the cyclical behavior of firms’ policies affects agents’ consumption and thus marginal utilities through the stochastic discount factor. A convenient way to capture the persistent stochastic variation in agents’ consumption growth is to estimate a process, in the spirit of Bansal and Yaron (2004), from simulations of our model. A quantitative estimate

\footnote{The model is thus consistent with evidence that leverage is procyclical at refinancing points, while countercyclical in the cross-section, see e.g. Bhamra, Kuehn, and Strebulaev (2010), Danis, Rettl, and Whited (2014)}
for the dynamics of consumption growth in our baseline model is given by:

\[
\begin{align*}
    E_{g_{t+1}} &= 0.935 E_{g_t} + 0.262 \sigma_{g_t} \varepsilon_{t+1} \\
    \sigma^2_{g_{t+1}} &= 0.0081^2 + 0.971 (\sigma^2_{g_t} - 0.0081^2) + 0.249 \times 10^{-6} w_{t+1}
\end{align*}
\]

where \( g_{t+1} = C_{t+1}/C_t \) is the realized consumption growth, \( \sigma_{g_t} \) is the conditional volatility of \( g_{t+1} \), and \( \varepsilon_{t+1} \) and \( w_{t+1} \) are i.i.d. shocks. While consumption is endogenously obtained in our general equilibrium model, we note that its growth rate exhibits both a fair amount of persistent long-run variation as well as endogenous time variation in its conditional volatility.\(^{20}\)

This estimated consumption growth process reveals how the model generates endogenously conditional movements in risk that must compensated in asset markets. Table 4 documents this by showing how the popular indicators equity and credit market condition, such as valuation ratios and credit spreads, are informative about long-horizon stock market excess returns. As in the data, high price-dividend ratios predict lower expected stock returns going forward, while credit spreads forecast high average stock returns.

While some of the patterns regarding cross-sectional and time-series predictability in returns are reminiscent of the literature studying the links between growth options and returns (see e.g. Gomes et al (2003), Gala (2010), Garleanu, et al (2012)), our work is distinct by linking movements in quantities and risk premia to credit markets. We now examine the role of credit markets for our results more closely.

### 4.3 The Role of Leverage and Credit Risk

#### 4.3.1 Aggregate Moments

Table 5 provides insights into the role of leverage for aggregate fluctuations and risk premia by comparing the main macroeconomic and financial statistics for a variety of alternative model specifications.

First, and foremost, and all equity version of our economy does not generate enough volatility

\(^{20}\)To compare with Bansal and Yaron (2004), we time aggregate their model to a quarterly frequency, and obtain:

\[
\begin{align*}
    E_{g_{t+1}} &= 0.939 E_{g_t} + 0.151 \sigma_{g_t} \varepsilon_{t+1} \\
    \sigma^2_{g_{t+1}} &= 0.0022^2 + 0.962 (\sigma^2_{g_t} - 0.0022^2) + 8.282 \times 10^{-6} w_{t+1}
\end{align*}
\]
in equity returns and macro quantities and is also not capable of matching the observed equity premium. This model also produces an unrealistically high equilibrium risk free rate. Compared with this all equity economy, the unconditional volatility of consumption increases by about 35% in the baseline, levered, economy. Notably, the value premium implied by the all equity model, while still positive, is also substantially smaller. Intuitively, in our model, growth options are partially debt financed, so that value firms in the cross-section also exhibit higher leverage ratios. The cross-sectional differences in leverage between growth and value firms thus amplify the dispersion in equity risk. In the context of our model, this dispersion accounts for a substantial fraction of the observed value premium.\(^{21}\)

We next consider a version of the model where firms default on their debt obligations whenever their internal cash flows fall short of their debt obligations, that is, in case of a “liquidity” default. Formally, the default cut-off \((\bar{z})\) becomes:

\[
\bar{z}(b, x) = \min \{z : \exp(x + z) - \delta = b\} \tag{33}
\]

Now firms are prevented from covering liquidity shortfalls by contracting additional capital in equity and debt markets. As the table shows, this form of default has a slightly dampening effect on aggregate volatility. Intuitively, firms anticipate they will default earlier and more often, so they will take slightly less debt. Notably, however although default rates in this case are substantially higher, we see only a modest increase in average credit spreads. This is because default boundaries now tied to profitability not equity values, are far less sensitive to cyclical movements in the aggregate economy.

Finally, we consider the case with credit shocks, in the form of variation in the recovery parameter \(\phi\). As we can see this version of the model is calibrated so that the unconditional moments are essentially unchanged from the baseline specification.

Table 6 shows how these differences in assumptions about how credit markets work, affect cyclical patterns in firms’ financing and investment policies. Leaving aside the all-equity model,

\(^{21}\) Alternatively, while a positive value premium is consistent with models with irreversibilities in investment and operating leverage (Gomes et al (2003), Zhang (2005), Carlson et al (2006), Garleanu et al (2012)), our findings can be seen instead as ascribing a relevant component of the value premium to financial leverage.
the most notable changes occur when we allow for credit market shocks. This version of the model generally produces the most realistic cyclical patterns. This is because credit shocks impact both leverage and spreads directly but GDP growth only slowly, through changes in consumption and investment over time.

### 4.3.2 Leverage and Return Predictability

Tables 7 and 8 offer an in depth examination of the role of leverage in generating the patterns in time-varying expected stock returns documented above.

The easiest way to do this is by looking at the implications of an all equity model. In this case valuation ratios are still able to predict future equity returns, but the effects are substantially muted. To better understand this result it is useful to re-estimate the dynamics of consumption growth for the all equity version of the model, which yields:

\[
E_{g_t+1} = 0.814 E_{g_t} + 0.212 \sigma_t \varepsilon_{t+1}
\]

\[
\sigma^2_{g,t+1} = 0.0063^2 + 0.906 (\sigma^2_{g_t} - 0.0063^2) + 0.097 \times 10^{-6} w_{t+1}.
\]

Comparing with the benchmark model we see that now consumption growth exhibits less persistent long-run movements, while variation in volatility is both smaller and less persistent.

A popular variation of the all equity model is to simply “lever up” the equity returns exogenously by assuming firms have a constant leverage ratio, which is here set to the average for the baseline model. Tables 7 shows that this has almost no impact on the predictability regressions. Another useful thought-experiment, is to instead “lever up” the returns from an all equity model, by using an exogenous leverage process that matches both the mean and cyclical correlation of leverage in the baseline model. Tables 7 shows that accounting for realistic countercyclical movements in leverage, even if these are specified exogenously, significantly enhances return predictability. This suggests that empirically a large fraction of the movements in expected stock returns can be simply ascribed to realistic countercyclical leverage dynamics.

The baseline model further departs from this setting because the Modigliani-Miller theorem
does not apply, so that leverage and asset risks are jointly determined. Inspection of Table 7 shows that this joint interaction further exacerbates return predictability. Intuitively, absent Modigliani-Miller, firms’ financial decisions affect equilibrium consumption. In particular, long-term debt propagates the persistence of the consumption process, while procyclical refinancing further amplifies its stochastic variation.\footnote{Firms are less likely to pay the fixed costs associated with debt restructuring in low productivity times, raising effective average debt maturity and further depressing investment via debt overhang.} Allowing for credit shocks has only a relatively minor impact on the ability of price-dividend ratios to predict stock returns.

However, as Table 8 shows, credit shocks do increase the ability of credit spreads to forecast future stock returns. This occurs because now credit spreads encode additional information about credit market conditions affecting firms investment and financing decisions, which are reflected in stock returns going forward.

\subsection{The Cross-Section of Leverage and Default Risk}

All moments documented so far have been obtained by aggregating across the cross-sectional distribution of firms in our model. We now examine the properties and determinants of the firm distribution. As before we report quantitative results both for our baseline parameter choices and for a few alternative specifications to illustrate some of the mechanisms behind our findings. We also document how cross-sectional variation in firm characteristics is important for time series movements in the aggregate economy.

Table 9 reports a first set of results. Panel A documents properties of firm-level investment and financing policies along with their cross-sectional dispersion. The benchmark model is generally consistent with basic facts about corporate policies. Notably, the model reproduces the lumpy nature of firms’ investment and financing behavior quite accurately. Firms’ investment comes in rare but sizable spikes, as does equity issuance. Assuming liquidity default produces only a slight reduction in the amount of cross-sectional dispersion in our model, while adding credit shocks has no discernible impact on these properties.

Panel B shows that the cross-sectional dispersion of firm characteristics also exhibits some distinct cyclical patterns. While the cross-sectional dispersion of market leverage and credit spreads
widens in downturns, differences in firms’ investment opportunities are mildly exacerbated in expansions. As shown in Table 3 above, debt issuance is procyclical since firms are less likely to pay the fixed costs associated with debt restructuring in downturns. This makes effective debt maturity countercyclical, and implies that firms tend to be further away from the optimal capital structure, thereby widening the dispersion in leverage and credit spreads. In other words, the tail of the distribution of firms burdened with high leverage widens in recessions, rendering them more sensitive to additional disturbances.

Finally, Table 10 compares the model’s predictions to core conditional moments of the cross-sectional distribution of firm level leverage identified in the empirical capital structure literature. These are based in empirical regressions relating relating corporate leverage to several financial indicators (e.g. Rajan and Zingales (1995)). This table shows that our model reproduces the observed negative relationships between leverage and both profitability and Tobin’s Q. With persistent shocks, both highly profitable and high Q firms have large investment opportunities going forward. Because equity issuances are costly, such firms will borrow more prudently to avoid floatation costs. The table also shows the model produces a strong positive relation between firm size (measured by market capitalization) and leverage.

4.5 Other Parameter Choices

Table 11 examines the sensitivity of some of the main moments to some key model parameters. The table shows that when shocks to the stochastic growth rate are not sufficiently persistent, so that $\rho_x$ is lower, the model fails to generate enough volatility in equity returns and thus cannot match the observed equity premium. In this case the model also produces an unrealistically high equilibrium risk free rate. Similarly, lowering the persistence $\rho_x$, reduces default rates and credit spreads. Clearly, firms find it easier to avoid default when temporary bad times are expected to be shorter. In turn, equilibrium leverage ratios are higher than in the baseline case. Persistence has profound effects on the asset pricing implications of our model but does not significantly alter the level or volatility of the main macro quantities, at least not at these relatively short horizons.

Removing either equity issuance or debt issuance costs provides firms with additional financial
flexibility to cover cash shortfalls by issuing new equity or to refinance more cheaply. Not surpris-
ingly, this tends to dampen aggregate volatility slightly and produce a corresponding reduction in aggregate risk premia. Eliminating issuance costs also produces a small increase in average leverage.

5 Business Cycles

The previous section documented how credit markets have significant effects on aggregate and cross-sectional volatility and risk in our model. We now explore some of the macroeconomic effects of this friction and show how it produces both an endogenous amplification of shocks and, perhaps more significantly, it endows credit spreads with the power to predict future movements in output and investment.

5.1 Amplification of Business Cycles

Figures 4 look at the impact of fluctuations in credit markets on key macroeconomic quantities. Figure 4 directly compares the response to exogenous technology shocks in our benchmark economy with levered firms, to the response in an all equity model. Output, consumption and investment growth all respond by between 35% to 50% more to an increase in the level of aggregate productivity. Thus leverage introduces a powerful amplification mechanism because positive productivity shocks also reduce the probability of default and thus lower the effective cost of new debt. This raises ex-ante firm value and encourages firm creation and investment spending.\(^{23}\) These amplifications results are quantitatively similar to those in Bernanke et al (1999). This is because both models are calibrated to deliver similar shares of investment in output and average credit spreads. However, our transmission mechanism is quite different, and relies on movements in credit risk premium to produce realistic variation in credit spreads and the cost of capital.

\(^{23}\)Because we abstract from variations in labor supply these results are probably a lower bound on the amount of endogenous propagation that this mechanism can generate.
5.2 Predicting Business Cycles

We now investigate the ability of credit spreads to forecast movements in the aggregate economy in our model. Table 12 shows the results of regressing one year ahead growth in (log) output and investment, respectively, on the average (value-weighted) credit spread at time $t$. The table shows that elevated credit spreads forecast future declines in aggregate output and investment in ways that are statistically and economically meaningful. The estimated coefficients are similar in magnitude to those found in our empirical counterparts.

Within the context of our model, we also present additional results that shed new light on the economic mechanism underlying the predictive power of credit spreads. The table shows that this predictability survives even after we control for the current state of aggregate productivity, $x_t$. Recall that in the baseline model without credit shocks, aggregate variables such as output and investment, depend only on the two-dimensional aggregate state $s = (x, \mu(\cdot))$. Thus, unlike standard aggregate models there is here an important role for firm heterogeneity which is captured, to some extent, by variation in credit spreads. Intuitively, credit spreads contain information about firms in the tail of the distribution which are burdened by elevated leverage, those that are most likely to be plagued by debt overhang and imminent default.

We can also decompose the credit spread in two components, a risk neutral spread, that captures expectations of losses over a given horizon, and the credit risk premium, which accounts for the covariation of these losses with investors’ marginal utility. Table 12 shows that in our model the risk neutral credit spread component does not significantly forecast future movements in either output or investment, confirming the crucial role that risk premia plays in our model.

The lower panel of Table 12 recalculates these predictability regressions for the augmented version of our model with credit shocks. Formally, with credit shocks, the aggregate state space becomes $s = (x, \phi, \mu)$ and credit spreads now capture at least some of the variation in the last two. The results show how in this case credit spreads become somewhat more important in this world, especially regarding future investment.

6 Conclusion

This paper studies a general equilibrium model with heterogeneous firms making optimal investment and financing decisions under uncertainty, and brings together many core insights from asset pricing, capital structure, and macroeconomics. The model reconciles, in a unified framework, several core stylized facts about asset returns and many key features in macroeconomic aggregate and firm-level investment and financing variables. Specifically, we show that our model produces a sizable average equity premium and credit spread, together with plausibly low average returns on safe assets. It also implies that, in the time series, both price-dividend ratios and credit spreads have substantial predictive power for future stock returns, while generating a significant value premium in the cross-section of stock returns. A major contribution of our model is that it delivers an explicit connection between fluctuations in the cross-sectional distribution of firms and the time-series movements in macroeconomic aggregates and financial prices.

Endogenous movements in leverage and risk premia contribute to the amplification and propagation of aggregate consumption risks and volatility. This raises the volatility of the market price of risk and produces quantitatively realistic risk premia. Importantly, endogenous default also increases the volatility of consumption during recessions, as the mass of firms burdened by excessive leverage and closer to default grows. As a consequence, the equilibrium market price of risk also becomes sharply countercyclical. Countercyclical leverage drives up risk premia on financial assets in downturns which, in the time series, is naturally reflected in both price-dividend ratios and credit spreads. Cross-sectionally, because investment is, at least partially, debt financed, value firms tend to have higher leverage ratios and these cross-sectional differences in leverage between growth and value firms amplify the dispersion in equity risk, and are a major driver of the value premium.

In our equilibrium setting, endogenous default increases the volatility of consumption during recessions, thereby rendering the market price of risk sharply countercyclical. As a consequence, expected returns on stocks and bonds are higher in recessions, raising the cost of capital and lowering investment and output growth. Endogenous movements in credit markets allow our model to match the observed conditional and unconditional movements in both financial prices and macroeconomic quantities in a parsimonious setting.

Appendix: Properties of the Firm’s Problem

This appendix establishes some of the basic properties of main value functions used to describe the problem of equity and bondholders. In all cases we assume that the economy is in steady-state so the cross section distribution $\mu$ is constant over time.

Lemma 1. the market value of debt, $Q(\cdot)$, is increasing in $x$, $z$ and $\phi$

Proof Monotonicity in $x$ follows from the facts that $\bar{z}(\cdot)$ is decreasing (see below) and the recovery payment increasing in $x$. Monotonicity in $z$ follows from the persistence in (3) and the fact that the recovery payment also increasing in $z'$. Monotonicity in $\phi$ follows from the fact that the recovery payment increasing in $\phi$. □

Lemma 2. The normalized equity value $P(\cdot)$, is increasing in $z$ and $x$, and declining in leverage $b$;

Proof This follows directly from the fact that equity cash flows, $\pi(\cdot)$, net of investment spending, $i$, are increasing in $z$ and $x$ while declining in $b$. □

Monotonicity of the value function ensures the existence of a (unique) default threshold. In addition to these properties, we can show that limited liability which endows equity with an exit option and increases the value of uncertainty, implies that $P(\cdot)$ will be convex in $\exp(z)$.

Lemma 3. The default cutoff, $\bar{z}(\cdot)$, is increasing in the coupon $b$ and declining in $x$

Proof This follows from the fact that $P(\cdot)$ is declining in $b$ and increasing in $x$. □

Lemma 4. The investment cutoff, $\bar{i}(\cdot)$, is increasing in $z$ and $x$ and (weakly) decreasing in the existing coupon payment $b$. The optimal debt policy $\bar{b}(\cdot)$ is increasing in $z$.

Proof The monotonicity of the policy functions in $z$ and $x$ follows directly from Lemmas 1 and 2. In addition, higher $b$ might trigger the equity issuance indicator $\chi_e > 0$ to switch from 0 to 1, reducing $\bar{i}(\cdot)$ implied by (11). □
Appendix: Computational Details

Computation of the competitive equilibrium is complicated by the endogeneity of the pricing kernel, which embodies the equilibrium market clearing conditions through its dependence on aggregate consumption and wealth. The main difficulty here that these quantities are jointly determined with the cross-sectional distribution, $\mu$, a high-dimensional object.

Our solution algorithm exploits the parsimonious characterization of the distribution $\mu$ and relies on three basic techniques. First, in our model both consumption and wealth are endogenously growing. To obtain a stationary representation of these quantities, we divide them by the aggregate capital stock $K$, which shares the same endogenous stochastic trend. Accordingly, we define $c \equiv \frac{C}{K}$ and $w \equiv \frac{W}{K}$. Second, we re-normalize the value functions for debt and equity to express them in units of marginal utility which is computationally more convenient. Third, following Krusell and Smith (1998), the cross-sectional distribution $\mu$ is approximated by a low-dimensional state variable that summarizes the relevant information in $\mu$.

The expression for the pricing kernel (23) guides both our choice of the approximate state space and the re-normalizations. To that end, we define the function:

$$p(c, w) = c^{-\frac{\gamma}{\kappa}} w^{\kappa - 1}.$$

Next, for any generic financial claim $V$ in our model, we define $\hat{V}(s, z, b) = V(s, z, b)p(c, w)$, which allows us to rewrite the corresponding recursions in a computationally more convenient form.

For simplicity, we illustrate the procedure using the inaction value of equity, $\hat{P}^0(b, z, s)$, using the representation

$$\hat{P}^0(s, z, b) \equiv P^0(s, z, b)p(c, w)$$

The other relevant normalized value functions $\hat{P}^I, \hat{P},$ and $\hat{Q}$ are defined accordingly. Our numerical strategy is based on numerically iterating on these value functions to obtain individual policy

\footnote{Note that any $V$ is normalized by construction, as it is expressed in per unit of capital terms}
functions and then aggregate. The value function for $\hat{P}^0$ satisfies:

$$
\hat{P}^0(s, z, b) = \max\{0, \max_{b'}\{\chi_e(1 + \kappa_e)\pi(b, b', z, s)p(c, w) + E\beta^\kappa\left(\frac{c(s') + w(s')}{w(s')}\right)\left(\frac{K(s')}{K(s)}\right)^\zeta \int_{\bar{s}(b', s')} \hat{P}(b', z', s')N(dz'|z)}\},
$$

where $s = (x, \mu)$ denotes the aggregate state and the term $(\frac{K'}{K})^\zeta$ with $\zeta = -\kappa/\sigma - \kappa - 1$ comes from the detrending procedure. Clearly, the value function depends on the cross-sectional distribution as $c$, $w$ and $K$ do.

In the spirit of Krusell and Smith (1998), we choose a low-dimensional approximation of the high-dimensional state space by means of variables that capture the relevant information embedded in $\mu$ well. Similar to Krusell and Smith’ approach, most of the current literature uses the aggregate capital stock $K$ as a sufficient state variable. In our setup, where tails of the firm distribution carry important information about pricing, this is insufficient. Rather, we choose to approximate the state space by means of the current aggregate shock $x$ and current consumption (relative to trend) $c$, so that we set $\hat{s} \equiv (x, c)$. Using $c$ as a state variable is natural in a model with heterogeneous firms as consumption reflects output and corporate policies of the entire firm distribution.

In order to solve for the functions, we need to forecast future consumption, wealth and the future capital stock, given current state variables. Again following Krusell and Smith (1998) we parameterize both the law of motion for aggregate consumption $c'$ and the growth rate of the capital stock as log linear functions of the aggregate state, $x$ and $c$:

$$
\log c' = \alpha_0 + \alpha_1 \log x + \alpha_2 \log c
$$

$$
\log(\frac{K'}{K}) = \eta_0 + \eta_1 \log x + \eta_2 \log c
$$

for some coefficient vectors $\alpha$ and $\eta$. Finally, it is straightforward to determine wealth using the no-arbitrage condition $W(s) = C(s) + EM(s, s')W(s')$, whose detrended version,

$$
W = c + E\beta^\kappa\left(\frac{c'}{c}\right)^{-\frac{\zeta}{2}}\left(\frac{w' + c'}{w}\right)^{\kappa-1}\left(\frac{K'}{K}\right)^{\kappa(1-\frac{1}{\sigma})}w'.
$$
can be determined efficiently using value function iteration, given the forecasting rules above for $c'$ and $K'$. 

With these rules at hand we compute firm value and policies. Note that we need to solve for the value functions simultaneously, as equity values and bond prices are jointly determined with default boundaries. These are then aggregated and checked for consistency using the general equilibrium condition (26).

More precisely, we use the following iterating procedure:

- Discretize the state space by choosing discrete grids for $b$ and $c$, and the shocks $x$ and $z^{26,27}$.
- Guess initial vectors $\alpha^0$ and $\eta^0$.
- Iterate on the functional equations for $\hat{P}^0$, $\hat{P}^I$, $\hat{P}$, and $\hat{Q}$ and compute decision rules for investment, default and leverage.
- Simulate decisions rules and compute the implied equilibrium allocations for $C$ and $W$. We obtain the equilibrium time series for $C$ by clearing the market each period using a bisection method.
- Use implied time series for $x$, $K$ and $c$ to revise log linear rules for $c'$ and $K'$ and check fit.
- Iterate until convergence.

All of our forecasting regressions have $R^2$s above 0.99, and adding additional state variables (such as the cross-sectional standard deviation of capital or coupon payments) do not change the results. As an additional accuracy test, we check that the implied wealth, computed as the aggregate equity and bond values plus tax proceeds, coincides with the aggregate wealth as obtained from the no-arbitrage recursion.

---

26 As $b$ is a function of both $x$ and consumption $c$, so $nb = nx \times nc$, where $ni$ is the number of points in the grid for $i = b, z, x, c$.

27 We use the procedure in Rouwenhorst (1995) since are highly persistent.

This table reports unconditional sample moments generated from the simulated data of some key variables of our benchmark model. We report averages across 1000 simulations of 64 years, corresponding to our empirical sample. All data are annualized. The return on equity refers to the value weighted aggregate stock market return, and the credit spread is the value weighted as well. The parameter values used in the benchmark simulation are reported in table 2. Data counterparts come from the BEA and CRSP.
This table reports business cycle properties of key macro and financial variables across model specifications. Data from the model comes from averages across 1000 simulations of 64 years. For flow variables we use correlations between growth rates. For leverage we report correlation with end of period ratios. Empirical sources are the Bureau of Economic Analysis and the Board of Governors of the Federal Reserve.

</table>

This table reports excess stock return forecasts for horizons of one to five years using the value-weighted credit spread $r_{t+n} - y_t^{(n)} = \alpha_n + \beta CS_t + \epsilon_t$, in various model parameterizations. The results refer to population estimates.

This table reports unconditional sample moments generated from the simulated data of some key variables of our model under different parameter specifications. We report averages across 1000 simulations of 59 years. All data are annualized. The return on equity refers to the value weighted aggregate stock market return. The parameter values used in the benchmark simulation are reported in table 2. Data counterparts come from the BEA and CRSP.
This table reports forecasting regressions for output and investment growth in both model specifications and the data. We regress 4-period ahead log growth in output and investment, respectively: \( \Delta Y_{t,t+4} = \log Y_{t+4} - \log Y_t \) and \( \Delta I_{t,t+4} = \log I_{t+4} - \log I_t \) on the value weighted aggregate credit spread \( CS_t \) at time \( t \), and additional control variables. The risk-neutral credit spread \( CS_t^{RN} \) is spread on bonds valued using the risk-neutral measure. T-statistics are reported in parentheses below. Statistics for the model are obtained by averaging the results from simulating the economy 1000 times over 64 years. Standard errors are corrected using Newey-West.
Figure 1: Equity and Debt Values. This figure plots the equity and debt value functions, $P(b, z, s)$ and $Q(b, z, s)$, respectively for our baseline calibration. The top panels shows the impact of a one standard deviation increase in aggregate productivity, $x$ while the bottom panels show the effects of a one-standard deviation increase in $z$. 
Figure 2: Optimal Policy Functions. This figure plots the policy functions for investment, \( \bar{i}(b, z, s) \), debt \( \bar{b}'(b, z, s) \) and default, \( \bar{z}(b, s) \), for our baseline calibration. The top panels shows the impact of a one standard deviation increase in aggregate productivity, \( x \) while the bottom panels show the effects of a one-standard deviation increase in \( z \).
Figure 3: Cross-Sectional Distribution of Firms. This figure depicts the equilibrium cross-sectional distribution of firms, $\mu(s, b, z)$ for our baseline model. The top panel shows the impact of a one standard deviation increase in aggregate productivity, $x$ on $\mu(cdot)$ while the bottom panel shows the effects of a one-standard deviation decrease in $x$. 
Figure 4: Business Cycle Amplification. This figure shows the response of output, consumption and investment growth to a one standard deviation positive innovation in aggregate technology in both our baseline levered economy and an alternative scenario where all investment is financed with equity alone.
